MEDICAL SECRETARY Mediscera Westcent London

The address of the Irish Office of the British Medical Association is 18 South Frederick Street, Dublin (telegrams *Bacillus Dublin* telephone 62550 Dublin) and of the Scottish Office 7 Drumshugh Gardens, Edinburgh (telegrams *Associate Edinburgh*, telephone 24361 Edinburgh).

QUERIES AND ANSWERS

DELAYED MENSTRUATION

A NUMBER of correspondents have replied to A.E.'s inquiry on November 3rd (p. 828) for advice as to the treatment of delayed menstruation in a woman aged 25.

Dr E. G. MUIR (Glasgow) reports the case of a woman aged 28 with a history of amenorrhoea for two years. The patient (he says) weighed 14 st 9 lb. her mentality was apparently but not so fully low. her voice was deep and husky, and there was a tendency to hair growth on her chin and lip. She was given ultra violet radiation in amounts ranging from a tonic to an erythema three days a week and thyroid extract to the limit of her tolerance. At the sixth week of treatment she not only had a period but her general attitude towards life was improved and she steadily lost weight.

Dr L. CUNNINGHAM (London N.W.) thinks that the symptoms of A.E.'s patient may be associated with some disturbance of the development of the uterus. He suggests prescribing oestrogen which contains the hormone of corpus luteum and has been shown experimentally to cause increase in the growth of the uterus in rabbits and to give the oestrous test

In rats. In a similar case he gave two tablets of agomemsiu thrice a day and an ampoule of sstomemsiu intramuscularly every third day, with good effect, which was afterwards maintained by using the tablets alone.

Dr G. D. FAIRLEY (London, W.C.) Dr W. G. BURNS (London, W.C.) Mr B. B. Loud "C. W. A." and "S. W." also report favourable results from the administration of sstomemsiu and agomemsiu.

EGG PRESERVATIVES

Dr T. D. HARRIS (Aberystwyth) writes. In reply to the inquiry of R. B. G. on November 10th (p. 878) whether any harm to the consumer can result from eating eggs preserved in water glass I may mention that in 1927 I was consulted by three maid servants who were ill after indulging freely for over a week in preserved eggs. The eggs had been in the water glass for about nine months and several were cracked. I wrote to Mr John Hargreaves, I.C., I.C.S. (an authority on silicates) asking his opinion as to the action of water glass on eggs. Mr Hargreaves replied that water glass could hardly affect eggs with unbroken shells but suggested the trial of milk of lime. An analysis of eggs that had been in water glass for a long time would be useful and interesting.

INCOME TAX

Assessment of Partners

"A. C. G." and his partner have been assessed for fifteen years as independent practitioners and he inquires as to what difference, if any, the making of the assessment in future as for a firm, will effect.

* * * The fact that the assessment will be made—as is legally the correct course—on the partnership in respect of the income of the practice will not make any difference to the amount of income tax payable. The allowances will be due to each partner as against his share of the assessment, and in substance the assessment will merely be an aggregate of the amounts which would have appeared on separate assessments. The partners will remain liable to separate assessment in respect of any non-partnership income, and will show their respective shares of the firm's liability in their statements of total income—the "amount of tax" payable is not shown. If either partner desires his co-partner not to be informed as to the amount of his allowances—for example, from life assurance—the only way to avoid having that amount shown on the partnership notice of assessment is presumably to arrange with the Inspector of Taxes for the allowance to be given in some other way—for instance by repayment or by set-off from any other income tax that may be payable.

Cash Basis

"A. G. C." is in the second year of his partnership and has hitherto been assessed on the basis of 'bookings'. He inquires whether it is not possible to transfer to the simpler basis of cash receipts.

* * * It has to be admitted that the 'bookings' basis is legally correct and that the cash basis can properly be applied only where it is more convenient and where the circumstances are such that the amount of cash received in any particular year is approximately equivalent to the value of that year's bookings. It is, however, always very difficult to persuade the revenue authorities to depart from the legally correct basis where it has once been applied and in addition a newly formed practice such as this one may very well be receiving in cash less than the true gross income on the basis of the value of the year's bookings.

Acquisition of Additional Practice

A and B purchased an additional practice in March 1928 for £1200. For the year 1928-29 the Inspector of Taxes wishes to add to what would otherwise have been the amount assessed for that year a sum of, say, £203 as representing the additional income derived by A and B. Is this right?

* * * Yes. A and B have succeeded to the small practice previously carried on by X and are assessable for 1928-29 in respect of the income from the combined practice on the profits of A and B plus those of X for 1927-28. The cash basis cannot be applied to the whole (now) practice without qualification in such circumstances. The £1200 represents an outlay of capital to acquire a source of income and no part of it can be treated as a professional expense.

LETTERS, NOTES, ETC.

VARIOLA FOLLOWED BY HERPES

Dr N. GRAY HILL (Garshilton) writes. With reference to Dr Lyth's very interesting memorandum (October 20th p. 700), it may be noted that, although cases in which a typical herpes rash follows varicella appear to be very rare they have from time to time been reported. Willcox and Rolleston (*British Journal of Children's Diseases*, October-December 1926) describe the case of a boy, aged 4, who first developed a characteristic eruption of herpes of the left side of the chest and four days later a generalized eruption of varicella. G. Dudley (*British Medical Journal*, August 22nd 1925) records the case of a boy aged 7

who complained of pain in the upper part of the chest for five days and then developed a herpes of the third left dorsal nerve and a generalized well marked chicken pox eruption. Onslow Smith and Williamson (*British Medical Journal*, March 5th, 1927) described a somewhat similar instance of a boy, aged 10, in which the herpes preceded the varicella by two or three days and Trolster and Doland (*Bulletin de la Société des Hôpitaux de Paris*, May 29th, 1925) record still another case in which a generalized varicella like eruption followed twenty-four hours after the appearance of herpes. A great number of cases have been recorded in which the medical practitioner has found both the herpetic eruption and the rash of chicken pox present at the same time but careful record has not been made as to which was the first to occur or whether they appeared simultaneously. For the herpes to precede the varicella seems, however, to be the more common. Afzelius mentions the case of a woman, aged 68, in whom an occipital zoster was followed seven days later by a generalized rash. Maloney demonstrated a very similar occurrence at the New York Academy of Medicine on October 3rd, 1922 and others have been recorded. Epidemics, even small outbreaks of herpes zoster seem to be exceedingly rare, and if any have been observed they would be well worth recording. Cases of symmetrical herpes encircling the trunk are also rare although a certain number are on record.

FORMALIN IN THE TREATMENT OF CANCER

Mr J. D. McFEE (Liverpool) remarks that since the publication of his paper on the treatment of cancer by formalin which appeared in the *British Medical Journal* of November 8th, 1902 (p. 1523) little attention has been devoted by others to this method. Very satisfactory results were obtained by him in cases of rodent ulcer, sarcoma of the hard palate, laryngeal cancer and epithelioma of the lip, injections of pure formalin being used in some instances and surface applications in others. He writes: "I feel thoroughly convinced that the treatment by pure formalin of malignant growths—especially primary or in the early state of recurrence—meets the requirements of what is admitted to be a cure for cancer—namely, the destruction of cancer cells with which it comes in contact, without material interference with the growth of normal tissue. It is true that formalin may destroy normal cells if pushed too far. The important point is, therefore, after removal of the cancer growth, to touch the edges of the wound once daily, when formalin will be found to stimulate normal growth and not to destroy healthy cells. My practice was to discontinue the frequent application of it to the edges of the wound after normal cell growth was well established, or alternatively to use it more sparingly every second or third day. As regards the limitations of the treatment, I do not think it can be expected in the case of any, a second or third recurrence with a large area of infiltrated cancerous tissue, that formalin will give satisfactory results. Surely there can be found, say, ten surgeons of good will to give a fair, honest, and exhaustive trial to this treatment and to publish the results."

HAEMOPHILIA IN THE TROPICS

Dr J. TERTIUS CLARKE (Harrow) writes. I notice in the *Journal* of November 10th (p. 844) a memorandum headed "Haemophilia in the tropics." The case is described as occurring in the Southern Punjab and the letter is addressed from Amhala. May I point out that no part of the Punjab is in the tropics and that Amhala lies about 420 miles north of the tropic of Cancer? The mention of geographical distribution of disease almost always engenders climatic influence and I believe I am right in saying that the climate of the Punjab is unlike that of any part of the tropics.

MEDICAL TREATMENT IN CHINA

F. BARLOW, R.N. writes. I am stationed near Yangtze and have been at Chungking, China, in the very heart of China. I feel that I can reply to Fleet Surgeon Home's letter (August 4th p. 228). I have made inquiries concerning Chinese doctors, and find that the statement with regard to their fees is partly correct. A wealthy Chinaman pays his medical adviser a fixed salary. For this the doctor must treat his patron, he must also attend to any of the dependants in the surrounding villages free of charge. But on "joss" days the doctor can demand a gift of money as offering to the gods, to protect the interests and to insure the health of his patron.

MISS AT THE COLLEGE OF SURGEONS

WE learn that the catalogue of manuscripts in the library of the Royal College of Surgeons of England, reviewed in our last issue (p. 858), has not been placed on sale. Copies of the book may, however, be obtained from the Librarian at the College, Lincoln's Inn Fields, W.C.

A DISCLAIMER

MR. ALEX. C. ROCHE (R.C.S. (London, W.)) would like it known that the mention of his name at a recent inquest on a case with which he had no connexion was without his knowledge and consent.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 49, 50, 51, 54, 55, and 56 of our advertisement columns and advertisements as to partnerships, assistantships and locum tenencies at pages 52 and 53. A short summary of vacant posts notified in the advertisement column appears in the *Supplement* at page 227.

Observations

OF

THE EARLY TREATMENT OF THE PSYCHOSES
AND PSYCHONEUROSES *

BY

A HELEN BOYLF, M.D.,

Honorary Senior Medical Officer, Lady Chichester Hospital for
Women and Children, Hove

We all want the best treatment at the earliest practicable moment for the psychoses and psychoneuroses, as for all kinds of disease. On that we are agreed, although we may differ as to what that is, as to how best to set about obtaining it, and as to the size and nature of the problem.

The discussion divides itself naturally into two parts (1) *early treatment in the individual*, and, having evaluated this as to the size of the demand for it, its importance, at what stages it should be undertaken, and so on, to consider, in the event of a decision in its favour, (2) *how we can best attain it*.

The psychoses and the psychoneuroses are diseases which have been much discussed and still have a blurred outline, and this is inevitable, for the pathology is often obscure.

The first proposal I would make towards the attainment of early treatment is to scrap both those unclear words, which Dr Bernard Hart has done in his splendid little book *The Psychology of Insanity*. It would be far better to revert to the old description by symptoms: depressed, excited, or disturbed, as the Americans have it, maladjusted, anxiety states, phobias, kleptomania, etc. Meantime, as the title thrusts these unwelcome guests upon us to-day, it may be said that under the heading "psychoses" there seem to be included the various forms of insanity, while under that of "psychoneuroses" are grouped the mental disturbances which are not insanity. If, however, we are going to talk of early treatment we must recognize that insanity begins before a person is insane—that is, that the insane paranoid with delusions of persecution shows signs of this attitude to life, this habit of mind, with its belief that the other members of the herd are against him, for a long time, probably for years, before he develops recognizable delusions or insane behaviour and is regarded as insane. In other words, for a long time he was forming a paranoid adjustment to life, while still sane, which by no means always results in definite insanity, any more than, to use a physical analogy, every case of tuberculous infection develops into fatal tuberculosis. No one doubts that the treatment of tuberculosis should be undertaken at the first sign of it, nay, even before there is a sign, in the pre-tuberculous stage in children. I submit that the same sound line of action should be taken with regard to the onset of mental and nervous disorders.

In demanding early treatment on a wide scale for individuals we may be asked what evidence there is that the need is a great one.

We have evidence in the report of the Board of Control that a large number of persons are suffering from definite insanity—"135,626 were notified insane" and under care in England and Wales on January 1st, 1927. All these patients have been at one time early cases, in some the developing period may have been short, but in many it has been long. Of these, 120,911, or "88.5 per cent of all notified insane," were rate-aided patients and therefore a serious burden on the community, 874 were criminals (of whom 399 were charged with murder), who are not only now being supported by the country, but who have besides taken a heavy toll in the protective measures, in police and courts, that they impose upon us, and in the anxiety, worry, and loss that they have caused. In addition to the above there were 796 voluntary boarders. If to these are added 35,167 mental defectives "subject to be dealt with," and 25,067 who may become "subject to be dealt with"—that is, 60,234—and it is also recognized that in

many cases ascertainment is entirely inadequate, the size of the problem of mental health begins to show itself insano, mental defectives, and voluntary boarders—197,656.

Admitting that early ascertainment and treatment in the case of mental defectives will not lead to cure, it can in many cases protect the community by helping to make the patients partly self-supporting or less dependent, and by segregation it can obviate the possibility of their bringing mentally defective children into the world and release them from a hopeless battle with life, for which they are insufficiently equipped.

With regard to the insane cases—while there are still some die-hards who are entirely fatalistic about mental disease, believing that, like the wind, it bloweth where it listeth and nothing can be done about it, there is a growing belief that, while heredity and inherent constitution have great influence, in some or many cases they form a fertile ground only, and that if seeds of mental disorder are not planted and cultivated by events and environment there is a reasonable probability of escape. It is possible that the expert safeguarding may have to start in early days, and that the proposed child guidance clinics will be the first line of defence against adjustments to life which may later develop into paranoid trends, the formation of fantasies to the exclusion of a faithful tackling of life and its difficulties, the acquirement of regressive tendencies leading to fixation and a childish outlook, or the protean forms which may be evolved in the effort to make tolerable what appears to be an intolerable situation. The development of insanity follows the same lines as physical disease—the symptoms are evidence of Nature's effort to cure, or to adapt to an unsatisfactory environment. Fantasy-building, for instance, is a protective and healing mechanism in its proper place. It remakes a sordid world for us, it keeps hope alive, it guards happiness, it favours discovery, even to giving us the wings of a dove—a fantasy held in men's minds for many centuries before realization.

Fantasy (like the unnecessary formation of scar tissue in keloid), out of proportion to life, makes the introvert, passing later into dementia praecox and analogous states. We should see to it that this adaptation, if in faulty degree, is dealt with early. Surely as experienced and as carefully trained an expert is needed for the early stages of these mental cases as is required for treating eyes, throats, or noses. If this be so there is indeed a demand which should be met.

There is other evidence of failure to cope efficiently with the problem of mental health in the reports of the Prison Commissioners. In the last report attention is called to a residue of persons who, though not certifiable under either the Lunacy or Mental Deficiency Acts, "are in medical opinion in an unsuitable environment in prisons" owing to their mental state. "These people form a subnormal group and include the simple feeble-minded and those of borderline intelligence." These include "cases of mental deficiency", "imperfectly developed states of insanity, mental weakness after attacks of insanity," and so on. Of 77 such men, 41 had six to fifty-four previous convictions. Of 29 such women, 22 had six to 109 previous convictions. Is it too much to hope that with greater facilities for treating such cases they may be dealt with in a way more satisfactory to the community and themselves than is shown by the above figures?

There were 178 girls between 16 and 20 years old under sentence of imprisonment, and, without counting charges dealt with under Section 1 of the Probation Act, 47 per cent had been previously convicted from once to eleven times or more. There were 2,464 lads between 16 and 20, 50 per cent of whom had been previously convicted, 16 of them from eleven to twenty times, 2 over twenty. Surely with youngsters such as these it is not beyond the bounds of possibility to devise some psychological or medical approach which, undertaken early enough, should prevent this faulty adjustment to life. The recidivism is marked amongst adults also. 37,237 (64 per cent) men and 7,000 (87 per cent) women received during the year had been previously convicted, 2,945 men and 2,978 women had been previously convicted over twenty times. Is this a satisfactory result of the treatment we now accord to criminals, or, as I should

* Made in opening a discussion in the Section of Mental Diseases and Neurology of the Annual Meeting of the British Medical Association, Cardiff 1923.

like to call these recidivists, mental patients? It is interesting also to note that the numbers of these worst recidivists correspond roughly to the proportion of men and women in the country, and not to the number of the delinquents relatively.

In an appendix in a previous report the medical officer to Birmingham Prison writes

All abnormal conduct tends to be antisocial what we term criminal conduct is only one branch of the tree. The problem of the delinquent should not be envisaged apart from that presented by other mentally abnormal persons. Many of our cases present the problems of social maladjustment. Only the closest investigation will supply the clue for the rectification of them.

The fact that on admission to some prisons wise and humane regard is had to the mental condition of the prisoners, and measures are taken in many cases for ascertaining and treating it, is no valid argument against the necessity for facilities for the help of mental maladjustments outside. These very cases, if capable of being efficiently handled after conviction, would be a *fortiori* cases needing help before the maladjustment manifested itself in such antisocial conduct as to lead to conviction, and it should not be necessary to be sent to prison to secure this help and consequent health of mind.

Still further evidence of the need for expert work is exhibited in the *Criminal Statistics* published by the Home Office, which show that 4,408 suicides occurred in England and Wales in 1926, and 2,194 attempted suicides were known to the police—altogether 6,602. To these must be added a large number, probably the majority of attempted suicides, which have not come to the notice of the police, and some successful suicides which are never found out.

As well as these suicidal cases there are recorded a large number of sex offences known to the police. The total was 4,935. This included 126 cases of rape and 1,961 of indecent assaults on females. The remainder was made up of cases of indecent exposure (1,973), unnatural offences, incest, etc. While in no way minimizing the power of the human being to exert control, it may be suggested that, without staining probability unduly, it is more than likely that many of the above offences are evidence of want of mental balance. Also it is certain that all such cases are not known to the police, and that there are many which are responsible for marital unhappiness and the wreck of wholesome family life short of insanity. No one who has been in practice for long and has the intimate confidence of his patients can fail to have met these cases. All those who are concerned with nervous and mental work will know that they are many. Alcoholism also is often a sign of mental and nervous instability.

I am well aware that in adducing the above as evidence of the size and widespread nature of the problem of mental health, and of the need for the prevention and early cure of mental and nervous disease, I am laying myself open to the accusation that I am an empire-builder in this department, that I seize colonies illegitimately from others, and that some of the territory I have suggested as within the realm of mental medicine is really in that of Jurisprudence, Pedagogical Science, Ecclesiastical Authority, or Religion. Is this so? Is it not truer that all of these must co-operate to succeed, and that a League of Experts with intimate understanding and trust might discover a better way of helping man in his development than has yet been evolved? Has medicine up to now contributed its quota to the solving of these problems? Has mental medicine nothing more to say, no message with regard to these maladjusted people? It may well be that such a league may be a necessary corollary or precursor to the full functioning of the League of Nations.

The above by no means exhausts the numbers needing special help. There exists another, and larger class of patients, "unwept, unhonoured, and unsung" in any Government statistics. These are the so-called psychoneurotics, who while not insane, nor mentally defective, nor delinquent, often suffer mental torture to a degree little understood. The patients at the few existing clinics for nervous and mental disorders are largely of this type. Their illness varies in degree from mild forgetfulness of time or things, slight insomnia, nervous dyspepsia, phobias such as fear of a mouse, a cat, or a thunderstorm, up to a state

when death may supervene, as in anorexia nervosa, or when suicide appeals as incomparably more attractive than the terror of existence in this world. These are the patients, far more numerous than is thought, for whom most can be done. It would be of interest to know how many of the chronic dyspeptics, gynaecological cases, rheumatic patients, in fact chronic cases altogether, which haunt the outpatient department of any general hospital—inevitable as the weather and quite as tiresome—are primarily or in part due to unsolved mental conflicts, to anxiety states with fear causing dyspepsia or diarrhoea, as it does acutely in many students before an examination.

A question often asked is, What type of patient is it that is meant by an early case and suitable for early treatment? Including in early treatment preventive measures, such as dealing with faulty mental attitudes in children as well as adults, the best definition that I can suggest is. Those who have special difficulty in their mental and moral adjustment to life. All of us have some difficulty, and it is a recognition of this fact which has led us to ignore early maladjustments in the hope, often ill founded, that they will be "grown out of." A tendency to regard such troubles as a dispensation of Providence or domination by the devil, and to struggle unintelligently for a foolish resignation, or submit to a sense of inferiority or a constantly recurring conflict, leads to inhibition, fatigue, and unnecessary expenditure of effort. We have only to consider the results attained by the National Institute of Industrial Psychology to see how important the work of an expert may be from the psychological side. It is easier to prevent a nervous breakdown than to cure one. It is also easier to prevent the strain and stress that comes from these maladjustments and psychoneuroses than it is to cobble up again the destroyed family life or the individual bankruptcy which may be the result of them. It is easier to promote mutual confidence and trust than to mend the tatters in the garments of industrial peace torn by the conflict of a strike. This idea of the connexion between industrial unrest and psychological maladjustments is no far-fetched fad of my own. In the last number of the *Journal of the National Institute of Industrial Psychology* Dr. Myers, after explaining that the methods used "follow precisely the familiar principle of bodily healing," said

"Is it surprising then that holding these views and proceeding along these lines the Institute has met with such success in increasing both output and contentment in actual practice and with such widespread approval not only from the more progressive employers but also from the workers and the trade unions of this country?"

The mental readjustments secured (combined with physical ones) are making for trust and understanding. This is surely closely allied to, if not part of, mental medicine.

To sum up so far. Many if not most of the difficulties found in education, criminology, religion, industry, general medicine, and in securing the peace of the world can only be solved with the aid of mental medicine, an understanding of the mind of man, in health and disease. No doctor would admit that an understanding of the body in health was foreign to his purpose of grappling with disease. No doctor should any longer admit that an understanding of the mind in health is redundant, and still less of the mind diseased. The intricacies of its connexion with the body still need elucidating, and are intimate and inmovable.

The psychoses and psychoneuroses in the individual provide useful material for this study. What are the first signs of these diseases? How do we recognize them? Can they be prevented or cured? In other words, are we pursuing a "mad for fire" ourselves in endeavouring to ascertain and recognize ever earlier signs and symptoms, in the belief that we may be enabled ultimately to prevent their development and to cure them in their early stages? Is it a fact that the psychoneuroses, and to a greater extent the psychoses, are dependent upon inherent or innate factors in the individual which are impregnable to any attack from outside, that we cannot hope to cure or greatly alleviate and that it is useless and wasteful of time to try? Surely not. It may at least be claimed that in many alleviation can be gained, and cure also in

some, if by that is understood a capacity for a satisfactory, or passably good, adjustment to life. This is analogous to physical diseases. You do not exactly cure an appendix by cutting it out. The physical condition is not perfect afterwards. You leave a scar and other damage behind, but it is worth it if you get functional success or improvement. In like manner a recovered pleurisy may leave adhesions. Illness and operations on the mind may leave scars, may cause pain, but you may secure functional success or improvement, and it is for a measure of this that we must look.

In searching for evidence that this is obtainable I must refer you to the reports and opinion of those who are engaged in doing this work, and though the number of these is still woefully meagre the widespread nature of the work they are doing in the country is very encouraging. The early treatment of recent cases in mental hospitals has improved immensely of late years. The hospitalization of asylums—a word coined, I believe, by Colonel Ford—is progressing apace, but I must ask you to dwell now not on the certifiably insane treated in mental hospitals, but on the patients whom it is harmful to certify or who are uncertifiable, and the large number of the maladjusted, the patients labouring under obsessions, phobias, inhibitions, and so on. These are the cases for which early treatment is so necessary if we wish to prevent the faulty adjustments, criminal and others, which I have tried to indicate in this paper.

At the Lads' Clchester Hospital, established in 1905 nearly a quarter of a century ago, I have had the honour to be senior honorary physician since its start. Here we find that the patients are thoroughly convinced of its value, and continue to apply for help in numbers which, though we have several times increased our number of beds, have proved the hospital to be still inadequate to cope efficiently with the waiting list.

The demand of patients for treatment we share with quacks—it is no necessary proof of value, but the sources from which the patients come are of more significance. We have analysed 100 consecutive cases in 1917 and 100 this last year.

Given that the demand and need for early treatment are urgent and widespread, how can we best attain it?

Facilities for Treatment in General Hospitals

I submit that the first and most important step now is to establish as soon as possible facilities in connexion with every general hospital in the country. The patients are attending at the hospitals now, and will always be more readily found there than anywhere else.

All the other specialties—eyes, throats and noses, teeth, and so on—have gone through the same initial stage of being obliged to start hospitals of their own, after which the general hospital takes the work on and complains of overlapping. Let us not waste time and money over this.

I suggest that the need for the treatment and its value are established by the work already done in this and other countries.

Dr Carswell was the pioneer who started wards for borderland patients in connexion with the Poor Law—in 1904, I believe. The Lads' Clchester Hospital was the first hospital for these cases.

The pioneer in providing out-patient facilities was the late Dr Ravner, who with energy and foresight, about 1889, induced the governors of St Thomas's Hospital to open an out-patient department for early mental cases. He was succeeded there by Dr Percy Smith, who had in 1900 started the second out-patient department for mental diseases at Charing Cross Hospital.

Since then many others have followed suit, notably Cardiff under your President. There has been a steadily growing recognition of the need by general hospitals both in London and the provinces.

Facilities in Separate Clinics

The Tavistock Clinic for out-patients, under Dr Crichton-Miller, opened in September, 1920, and also does fine instructional and propaganda work with courses of lectures for lay and professional people.

The question of beds is a more thorny one, and so far has been largely buried.

The Maudsley Hospital (177 beds), under Dr Mapother, owing its existence to the late Dr Henry Maudsley's generosity, aided by the late Sir Frederick Mott, was planned many years before it was started in 1923, after its previous use as a war hospital. It is carried on under very special conditions, and is a centre for training and research of immense value, supported by the London County Council. It would be impossible to have many of such elaborate and complete institutions—though possibly there should be several connected with universities for teaching purposes on the lines of Professor Robertson's scheme in Edinburgh.

The Cassel Hospital, under Dr Ross, made possible by the grand gift of about a quarter of a million by the late Sir James Cassel, is providing for those who can afford moderate fees. For many years the wealthy have been catered for.

No provision elsewhere can efficiently supplant treatment in the general hospitals. They are well known, convenient, and no one objects to go to them, the patients present themselves there in any case, the earliest cases are to be found there, the general practitioners, who have the best chance of seeing the first mental difficulties, are in close touch with the hospitals, where the appointment of a specialist in this particular work will do more to secure the treatment of this illness on the same lines as others than any other move that can be made. Cases can readily be referred to the mental and nervous department, and even what can take place between the members of the staff with regard to them. Thus co-operation is invaluable on both sides. Moreover, for the teaching of medical students it is essential.

It has been said that there are not enough experts to go round, and, on the other hand, that there is no object in qualifying specially for this work, for there are not enough posts to go round. These are mutually destructive arguments. Meantime, there are good county mental hospitals all over the country, whose staffs are often willing to help if required, and the suggestion of the British Medical Association that no officer already holding a whole-time post should be eligible would presumably only apply if an equally expert applicant appeared. The welfare of the patients comes first. There is little doubt that, given the posts, even honorary ones, suitable applicants will shortly qualify for them.

I submit that there should be no more difficulty in providing a complete department, with facilities for out-patients and beds, for this specialty than for any other. Admittedly it has its own peculiarities, but so have surgery, radiology, maternity, and others. Notable steps have been made in this direction by St Mary's Hospital, the Middlesex, which has a scheme also for reciprocity in nursing with St Luke's Mental Hospital, and some others. In my view these hospital departments should be free from any compulsory detention, so that there might be no question of interference with liberty. There should be no locked door, nor should definitely insane patients be admitted.

Child Guidance Clinics

Still earlier than those cases we have been considering are those of children who show maladjustments in school life or before, and for them the child guidance clinics offer useful help. They are, as before said, the first line of defence. Two are already in existence in England, and an elaborate one in London is being planned with American help.

Voluntary Boarders in County Mental Hospitals

Apart from the general hospitals and the institutions in connexion with the teaching universities, we need also to be allowed to send voluntary boarders to county mental hospitals. This is absurdly obvious, and agreed to by almost everyone, and yet has been held up for years because it has formed part of a debatable bill.

Permission to Treat the Early Insane Patient on two Doctors' Certificates

To compass early treatment another measure is needed also—that is, to allow certifiable patients to be treated on the certificates of two doctors only, for a limited time. It is the legal intervention which the patients and their friends dislike. Many people approve of it in theory, but

in practice—though few object to seeing two doctors and acting on their advice—all would like personally to avoid the magistrate.

These two last suggestions, however, deal with cases more advanced than those suitable for general hospitals, and it is the exceedingly early maladjustment that I am most concerned about.

To those who fear to advocate these reforms on account of the expense I would say that they will come slowly enough, however much we may push for them, and it is probable that measures properly thought out would lead to economy, industrial peace, and a happier race, and justify all expenditure. Early treatment for these badly oriented people is as necessary, and quite as profitable, to the country as for tuberculosis. Why should not funds be forthcoming from the same source?

Summary

To sum up I would suggest that it is desirable

- 1 That every general hospital should have facilities for treating early nervous and borderline patients
- 2 That child guidance clinics should be available for the young maladjusted children and be under the charge of doctors
- 3 That delinquents should have expert examination with regard to their mental adjustment—on the first offence—repeated if necessary
- 4 That voluntary boarders be allowed in county mental hospitals
- 5 That early insane patients should be able to be treated on two doctors' certificates
- 6 That vocational guidance should be available for all who wish it—as at the National Institute for Industrial Psychology—as a preventive measure against maladjustments and unrest
- 7 That every medical student should be obliged to devote some time to the study of all forms of mental disorder
- 8 That examining boards should require evidence of knowledge of all forms of mental disorder

It is better to pay for this than for insanity, delinquency, unemployment, and industrial unrest. May we all live to see a goodly measure of the above reforms in this our beloved and on the whole stable country.

THE HISTORY OF SCARLET FEVER *

BY

J. D. ROLLESTON, M.A., M.D., M.R.C.P., F.S.A.,
Medical Superintendent, Western Fever Hospital, London

THE study of the history of scarlet fever is beset with two chief difficulties, inasmuch as, not only in the remote past, but until comparatively recent times, it was often almost impossible to disentangle the description of scarlet fever from that of other acute exanthemata, especially measles and erysipelas, on the one hand, and from that of diphtheria on the other.

An attempt has been made by some writers to trace back the history of scarlet fever to classical antiquity. Some, such as Malfatti, Collier, and Clifford Albbutt, have tried to identify it with the celebrated pestilence of Athens which occurred in the year 430 B.C., but the description given by Thucydides (Lib. II, cap. 47-54) indicates typhus rather than any other acute infectious disease.

Sanné remarks that certain passages in Hippocrates have given rise to the belief that the Father of Medicine was familiar with scarlet fever, owing to his speaking of an illness attended with a severe sore throat though he makes no mention of a rash. As Sanné points out, however, the mere existence of ulcers on the tonsils does not justify the diagnosis of non-eruptive scarlet fever. The same objection applies to writers such as Willan, who think they have found allusions to scarlet fever in certain passages in Celsus, Caelius Aurelianus, Aretaeus of Cappadocia, and Aetius of Amida, whereas diphtheria was probably the disease in question.

Herodotus, a physician belonging to the pneumatic sect, who flourished at Rome under Trajan about half a century before Galen, is credited by Bateman with having described "with considerable precision" the rashes of scarlatina as well as those of measles and small-pox. Bateman's account, however, is far from convincing.

The Arabian physicians, such as Avicenna, Ali Abbas, and Rhazes, have also been credited with allusions to scarlet fever. Rhazes, for example, stated that measles of vivid coloration was more dangerous than that which was but moderately red. It is but useless conjecture, however, as Welch and Schamberg remark, to regard such sentences as references to scarlet fever.

The first undoubted description of scarlet fever in medical literature is to be found in a work by John Philip Ingrassias (1510-1580), who was first professor at Naples and during his last twenty years lived at Palermo, where he was equally celebrated as an anatomist and as a medical practitioner. In his book entitled *De Tumoribus praeeter Naturam*, published at Naples in 1553, he speaks of a disease popularly known by the name of "rossalia" or "rosania," which consisted of "numerous spots large and small, fiery and red, of universal distribution, so that the whole body seems on fire." "Some there are," he continues, "who think that measles is the same as rossalia, but we have often seen that the two affections are distinct, trusting in our own eyes and not merely in the description of others."

Willan has identified the pestilential sore throat described by Wierus as spreading through Lower Germany in 1564 and 1565 as epidemics of scarlatina anginosa. It was particularly fatal to infants, and the sore throat was accompanied by violent fever, vomiting, swelling of the parotid glands, and an erysipelatous rash.

The next most important writer on scarlet fever was Baillon (Ballonius), who, under the title of "*rubiola*," described the principal varieties of the disease, including scarlatina anginosa. In an epidemic which occurred in Paris in the winter of 1574-75 there was a very high mortality, and medical art was of no avail.

Jean Cottyn of Poitiers, a contemporary of Baillon, in his work entitled *De febre purpura epidemiale et contagiosa libri duo*, published in Paris in 1578, is generally credited with having given the first description of scarlet fever in France, but Noirot considers his account is far from possessing the importance attributed to it by some persons who have probably never seen it. Cottyn describes the initial symptoms as general weariness, headache, redness of the eyes, sore throat, and fever which may be mild or violent. Some patients, he says, are comatose throughout the disease, while others are wakeful and restless. Purpura appeared on the second or third day, accompanied by delirium and soreness of the throat.

A much more important position in the history of scarlet fever is occupied by Daniel Sennert (1572-1637), who described an epidemic which occurred at Wittenberg in the beginning of the seventeenth century. He identified it with the rossalia of Ingrassias, and described the eruption in similar terms to those used by the Neapolitan writer (in statu vero universum corpus rubrum et quasi apparet ac si universali erysipellate laboraret). Sennert was the first writer to mention scarlatinal desquamation ("epidermide squamarum instar decedente"), the early arthritis ("in declinatione materia ad articularia transfertur ac dolorum et ruborem ut in arthritide excitat"), and post-scarlatinal dropsy and ascites ("mox pedes ad talos et suras usque intumescent"). It is noteworthy that though the occurrence of dropsy was recognized as a sequel of the disease before scarlet fever was given its name, it was not until two hundred years later, after the appearance of Bright's work in 1827, that its connexion with renal involvement was realized. The epidemic which Sennert witnessed was obviously severe and often fatal ("malum hoc grave et saepe lethale est"), and convalescence was protracted ("aegrique non sine magno labore et post longum tempus pristinae sanitati restituntur"). In more than one passage (*De febribus, Op. omni, T. vi, Lib. ii, cap. 12, pp. 483-484, Aegrius, Cent. II, Ep. 20*) he expresses his doubts as to what name he should give the disease. "I should have regarded it," he says, "as

* A paper read in the Section of History of Medicine at the Annual Meeting of the British Medical Association at Cardiff 1928.

erysipelas and some of our women call it 'Rottnuf,' but for the fact that it does not attack adults but only children. The vulgar look upon it as measles, and say of it 'Die Maseln laufen zusammen'."

Before taking leave of Sennert mention should be made of his son-in-law, Michael Doering, who observed an epidemic in Poland during 1625, and also noted the desquamation, rheumatoid pains, and anasarca characteristic of the disease. Contrary to what is stated by Norret and Sanno, he expressly mentions inflammation of the tonsils and surrounding parts among the symptoms of the disease (Sennert, *Epist.*, Cent I, Tp 88, Cent II, Lp 18).

In 1665 scarlet fever reappeared in Poland, where it was described by Simon Schultz under the name of "epidemie malignant purpura." In the following years it was observed by Ravger in Hungary, Ettmüller and Lange at Leipzig, Schrock at Augsburg, and Ramazzini at Modena. Ravger describes a case of which he was in charge in 1636, in a girl aged 20, and did not hesitate to identify it with the "rosalia" of Ingrassias. The patient not only had a dense rash, but also inflammation of the tonsils. "As the fever declined a windy tumour attacked the left hand whereby the fever was dissolved" (obviously a case of early scarlatinal arthritis).

The term "scarlatina" is generally supposed to have been first introduced into medical literature by Sydenham about 1675. Hirsch, however, doubts if he was the first to use the term, as in Lancellotti's *Monum. stor. Moden.*, 1, 208, 382, there is a reference under the year 1527 of persons dying of "malo da scarlatina." Goodall, in the latest edition of his work on infectious diseases, has also drawn attention to the term "scarlett fever" being used in Pepys' *Diary* on the date November 10th, 1664, the passage being as follows: "My little girl Susan is fallen sick of the meazles or at least of a scarlett fever." It is, however, an open question whether scarlet fever was really meant in either of these passages, especially in the last where Pepys applies the indefinite article to "scarlett fever."

Richter has pointed out that Sydenham's chapter on scarlet fever did not appear in the 1666 and 1668 editions of the *Medical Observations*, which were then entitled *Methodus curandi febres propriis observationibus instructa*, but was first published in 1683 at Amsterdam, only six years before Sydenham's death, in the first complete edition of his works, while the *Processus integri in morbis fere omnibus curandis*, which contains a shorter account of the disease in Chapter VIII, was first published in 1693, or four years after Sydenham's death.

Sydenham's description of scarlet fever in the *Medical Observations* (Sect VI, Chapter 2) runs as follows:

"Scarlet fever may appear at any season. Nevertheless it often breaks out towards the end of the summer when it attacks whole families at once and more especially the infant part of them. The patients feel rigors and shivering just as they do in other fevers. The symptoms, however, are moderate afterwards, however the whole skin becomes covered with small red maculae thicker than those of measles, as well as broader redder and less uniform. These last for two or three days and then disappear. The cuticle peels off and branny scales remain lying on the surface like meal. They appear and disappear two or three times."

The disease, in his opinion, was merely a moderate efflorescence of the blood arising from the heat of the preceding summer or from some other exciting cause.

As regards treatment Sydenham expressed himself as chary both of blood letting and elsters on the one hand and of cordials on the other. Complete abstinence from animal food and fermented liquors he regarded as sufficient treatment. Although the patient should keep indoors it was not necessary to stay continuously in bed. When the desquamation was complete the patient should be purged with some mild laxative suited to his age and strength.

By treatment thus simple and natural, he continues "the ailment we can hardly call it more is dispelled without other trouble or danger whereas if on the other hand we overtreat the patient by confining him to bed or throwing in cordials or other superfluous and over-learned medicines the disease is aggravated and the sick man dies of his doctor (*nimia medici diligentia*).

In the concluding paragraph he alludes to the possibility of fits or coma occurring at the onset of the eruption, for

which he recommends the application of a large blister at the back of the neck and a draught of syrup of poppies.

The mild character of the disease as Sydenham knew it is shown not only by what he expressly says ("hoc morbi nomen, *vix enim altius adsurgit*"), but also by his making no mention of the sore throat and of the complications of rheumatism and dropsy already described by Sennert and Doering. It is possible, however, as J. F. Payne suggests, that when Sydenham saw a bad case of scarlet fever he failed to recognize it as such. Payne adds that the inadequate description of the disease given by Sydenham largely contributed to the misunderstanding of scarlet fever and sore throats in the next century. On the other hand, inadequate as Sydenham's description undoubtedly was, we must be grateful to him for having established the autonomy of scarlet fever and given it a name to distinguish it from the other acute exanthemata, particularly measles.

It is, therefore, a regrettable fact that Sydenham's contemporary and successor Richard Morton maintained that scarlet fever was absolutely the same as measles, and only differed from it in the character of the eruption. "Let this fever," he says, "be expunged from the roll of diseases, unless it seem good to give it the name of confluent measles." Unlike Sydenham, he described a malignant as well as a mild form, and recorded eleven cases which had occurred in his own practice, in both children and adults, including two of his own daughters, aged 7 and 8 years.

Lake Sennert and Deering, and unlike Sydenham, Morton expressly mentions inflammation of the fauces in the acute stage and alludes to dropsy and ascites as sequels. He also appears to be the first author to note the occurrence of scarlatinal otitis, in a sentence where he speaks of an acrid and corrosive discharge of pus from the nose, ears, and throat (*Exercitatio tertia*, Cap 5).

In spite of Morton's attempt to identify scarlet fever with measles, the distinction established by Sydenham was henceforward accepted by subsequent writers in the seventeenth and eighteenth centuries, such as F. Hoffmann, Juncker, Cullen, Frank, and Vogel. Juncker in particular, in his *Compendium medicinae theoretico-practicae* (1724), adopts Sydenham's view of scarlet fever being an attempt of Nature to rid herself of acrid caustic matter, and as a harmless disease if left to itself, but likely to be troublesome if treated by a too hot regimen.

It is true that an attempt was made in the beginning of the nineteenth century by John and Piorry and Libérét to revive Morton's unitarian doctrine, the last two writers inventing the term "hème dermite morbillense" to include both scarlet fever and measles. Their views, however, did not meet with any acceptance.

Scarlet fever seems first to have been recognized in Scotland at the end of the seventeenth century. Sir Robert Sibbald, physician to Charles II, president of the College of Physicians of Edinburgh, and geographer of Scotland, in his work *Scotia Illustrata*, published in 1684, speaks of scarlatina as one of many other diseases which had arisen in that century, and suggests that it was due to the "depravities of the humours which have resulted from a growth of luxury." In the experience of Sibbald, who describes a case in the daughter of a judge of the High Court, the disease was rare and not often fatal.

According to Lützhoft the epidemic at Copenhagen in 1677, described by Ole Borch under the name of "rossalia squamosa," was scarlet fever and was probably the first outbreak of the disease in Denmark. It was not, however, until 1760 that the first Danish monograph on the disease, entitled *De febre scarlatina*, was published by Wernicke.

During the eighteenth century numerous epidemics of scarlet fever occurred throughout Europe and the United States, and were described by various writers, the best known of whom were Huxham, Fothergill, and Withering in this country, Storch and Zimmermann in Germany, De Haen in Holland, Plenciz in Austria, Rosen von Rosenstein in Sweden, Tissot in Switzerland, and Benjamin Rush in the United States, where scarlet fever first appeared in 1735.

Though scarlet fever was generally regarded in the eighteenth century as a distinct disease from measles, there

was a tendency to confuse it with angina maligna, which was not finally established as a distinct disease until the next century, when Bretonneau gave it the name of "diphthérie" in 1821. Withering, for example, at first was of opinion that scarlatina anginosa and angina gangrenosa were distinct diseases, but afterwards became convinced that they constituted but one species of disease, and Willan had no hesitation in ranking the "garratillo" among the varieties of scarlet fever. Cullen, on the other hand, expressed the opinion that scarlet fever was specifically different from angina maligna.

From perusal of the English writers in the first half of the eighteenth century, especially Huxham and Fothergill, who described epidemics of sore throat with and without a rash in Plymouth and London respectively, it appears that these were concurrent outbreaks of scarlet fever and diphtheria accompanied by some cases of ulcerative sore throat or pseudo-diphtheria.

Among the eighteenth century writers special mention must be made of Rosen von Rosenstein, who, in his work on diseases of children, describes the occurrence of scarlet fever at Upsala in 1741 and at Stockholm in 1761, and notes the appearance of secondary adenitis on the eighth or ninth day and of anasarca between the eighteenth and twenty-second. He is also one of the earliest, if not the first writer, to mention the possibility of a non-eruptive scarlet fever.

The disease, in his experience, varied considerably in severity.

The scarlet fever, he says, is sometimes and in some persons so favourable and gentle that the patient only requires a good nursing, whereas sometimes it is so lethal that it will carry off the patient in a day or two.

In like manner De Haen, after speaking of the mild form of scarlet fever seen by Sydenham, describes malignant outbreaks at the Hague in 1748 and 1749, and alludes to a malignant epidemic which had occurred some years previously in Belgium.

During the last thirty years of the eighteenth century, even when allowance is made for the prevalence of diphtheria, there was a considerable increase in the incidence of scarlet fever, epidemics of which occurred in England, France, Germany, Italy, Holland, Sweden, Denmark, and also in North America. The outbreaks for the most part were mild in character, but an epidemic in central Germany, which lasted from 1795 to 1805, was attended by an unusually high mortality, which was attributed to the abuse of sudorifics and stimulants.

In the commencement of the nineteenth century the tendency of malignant and extensive epidemics to be followed by periods of lesser prevalence and low mortality is well illustrated by the experience of Graves in Dublin and of Bretonneau in Tours. According to Graves the epidemic of 1801-4 was extremely fatal, death sometimes taking place on the second day, whereas the frequent epidemics which followed during the next twenty-seven years were always of a mild character. Subsequent epidemics of malignant scarlet fever which broke out in Dublin in 1831 and 1834 caused more deaths than cholera had done two years before or typhus did some years later.

Similarly Bretonneau, who had never seen a death from scarlet fever in his practice during the period 1789-1822, in less than two months of the year 1824 experienced an epidemic at Tours attended with so high a mortality that he came to regard scarlet fever as no less deadly a disease than plague, typhus, or cholera (Trousseau).

Bretonneau clearly differentiated scarlatinal angina from diphtheria by pointing out, first, that in scarlet fever the inflammation is widely diffused over the tonsils, palate, and pharynx, and is not, as in diphtheria, at first limited to one spot, and secondly, that the scarlatinal inflammation of the pharynx has no tendency to spread into the respiratory passages. Trousseau who is constantly acknowledging his debt to his old master, epigrammatically sums up the last distinction in the sentence "La scarlatine n'aime pas le larynx."

The chapter on scarlet fever in Trousseau's clinical lectures contains a masterly description of the disease, in which he not only develops the doctrines of Bretonneau, but also draws attention to the characteristic tachycardia,

fall of temperature by crisis, and frequent occurrence of albumina, and gives his celebrated account of the "formes frustes" or defaced types of the disease.

In the course of the nineteenth century several parts of the world which had hitherto escaped received their first visitation of the disease, such as Madeira in 1806, South America in 1829, Greenland in 1847, Australia and New Zealand in 1848, and California in 1849.

In his recent report to the Ministry of Health Dr. Allan C. Parsons points out that though it became possible, after the establishment of general registration of deaths by the Act of 1838, to compute rates of mortality from scarlet fever, the old confusion between malignant angina and scarlatinal angina prevented the earlier returns from being strictly comparable with more modern data. The mortality from scarlet fever in this country was undoubtedly very high for at least fifty years after the introduction of registration, the maximum being reached in 1863. During the last fifty-five years the mortality from scarlet fever in this country has shown a steady decline, which is particularly striking in comparison with that in eastern Europe, especially in Poland, Bulgaria, and Rumania.

Since the war an enormous advance has been made in our knowledge of the etiology, prophylaxis, and treatment of scarlet fever. Although Klein suggested a streptococcal origin for scarlet fever as long ago as 1887, there was a tendency until about five years ago to regard streptococci merely as secondary invaders. George and Gladys Dick, however, proved by experiments on human volunteers that scarlet fever is a local infection of the throat caused by a particular type of haemolytic streptococcus which is capable of producing a soluble toxin, absorption of which causes the general manifestations of the disease. In 1923 they successfully inoculated volunteers by swabbing their tonsils and pharynx with four days old cultures of the haemolytic streptococcus grown from the pus of a finger of a nurse who had contracted mild scarlet fever. In the following year by intracutaneous injection of the filtrates of the culture of the scarlatinal streptococcus, they devised a test, now known as the Dick test, which determines whether the subject is susceptible or immune to the disease.

Their results were confirmed by other observers, and although they have not found universal acceptance, especially in Germany and Italy, they have had far-reaching practical applications both in prophylaxis and treatment. Active immunization against scarlet fever has been undertaken on a large scale in the United States and on the Continent, especially in Poland, by injection of scarlet fever toxin modified or not by various methods, while a less durable immunity is conferred by specific scarlet fever antitoxin. A emetico serum, prepared by injection of a horse with the specific toxin, is one of the most valuable additions to therapeutics in recent years, and far surpasses in efficacy the use of the serum of convalescents, which was tried by a few clinicians some years previously.

Before the introduction of specific methods isolation of the patient was the only procedure which could be said to have had any prophylactic value. As in the case of diphtheria, however, in the pre-antitoxin era almost all the agents in the materia medica were tried in turn. The most popular preservative was belladonna, which was introduced by Hahnemann, the founder of homoeopathy, and enjoyed a considerable vogue for some time, especially in Germany.

Good results were claimed by Miguel of Amboise in 1834 from inoculation of the fluid obtained from puncture of the eruption, but he does not appear to have had any followers to confirm his results. The methods of treatment were also very varied, and included bleeding, cold or hot effusions, and a host of drugs of an emetic, purgative, diaphoretic, tonic, or narcotic nature.

THE LIGHT SENSE IN MINERS' NYSTAGMUS *

BY

R J COULTER, M B, B Ch, F R C S I,
Ophthalmic Surgeon Royal Gwent Hospital

I am fully aware that this communication is incomplete and inconclusive, but I have some hopes that it will open up a fresh aspect of the subject with which it deals, and induce others to investigate the changes which occur in the light sense in miners' nystagmus, and possibly find in it some help in elucidating the mysteries of that most complicated condition.

My attention was first directed to the subject by a paper read by Mr. Pernal at the Oxford Congress,¹ in which he stated that in all cases of miners' instagmus which he had examined he had invariably found the light minimum greatly increased, while their light difference was very little if at all greater than his own. At the same meeting he demonstrated the simple apparatus which he used in making the examination. It consists of black and white discs with sectors of white and black of varying sizes on them which, when rotated on pins, show grey circles of varying intensity. My tests have been made with this apparatus, but recently I have checked the light difference with Young's discs, and find that it is easier to work with them and that the results are similar so far as I can judge. Unfortunately Young's portfolio does not contain a light minimum test.

The accompanying table is founded on the records of

The Night Scene in 100 Cases of Others' Astigmatism

LIGHT MINIMUM				LIGHT DIFFERENCE			
Total	No Miners Vystagmus	Miners Vystagmus or Neurosis		Total	No Miners Vystagmus	Miners Vystagmus or Neurosis	
200	8	4 } 29	4 } 30				
100	51	2 } 29	6 } 30	100	51	25	25
50	31	12 } 16	19 } 25	50	35	14 } 19	21 } 30
25	7	3 } 16	4 } 25	25	11	5 } 19	6 } 30
15	3	1 } 16	2 } 25	12.5	3	0 } 19	3 } 30
100	45		55	100	45		55

Light Minimum—Normal or practically normal=59 per cent
reduced=41 per cent

Light Difference—Normal=51 per cent. reduced=49 per cent.

100 cases and the first thing that strikes one is that my results are exactly the reverse of Percival's as they show reduction in both the light minimum and the light difference in about 50 per cent of the cases. This naturally puzzled me, and on thinking the matter over I came to

A paper read in the Section of Ophthalmology at the Annual Meeting of the British Medical Association Cardiff 1928

the conclusion that Percival's observations must have been made on fresh cases, while mine were made on old ones, which were sent to me for examination with a view to ascertaining whether they had recovered. I wrote to Mr Percival, and he kindly replied, stating that this suggestion was correct, and that he agreed that both light senses are reduced in old cases. I have not been able to verify the observations on fresh cases, but if it is true that they have an increased light minimum which later turns into a deficiency it is a remarkable phenomenon. Percival attributes the early increase to an increase of endogenous stimulus and considers that this also accounts for the intolerance of light, but this latter may persist after the light minimum has become reduced. It would seem that either the increased endogenous stimulus must be sufficient to overcome the reduction in light sense which becomes manifest after it has passed off or that the reduction is something fresh which develops after the men have ceased working underground.

Coming to nine cases, and adopting Perceval's nomenclature and standard, only 8 per cent had a normal light minimum, but 51 per cent had the next grade labelled as 100, while in the remaining 41 per cent the light minimum was definitely reduced. I have divided these cases into two groups according to whether I considered from their other signs and symptoms that they were still suffering from miners' nystagmus or neurosis arising out of it, or had recovered. Of course this is only an opinion to be taken for what it is worth, but it indicates that, although 50 per cent of the cases with full light minimum still showed evidence of the disease, and one of those with the lowest grade measurable by the test was free from symptoms, there was a definite increase in the proportion of those still suffering from miners' nystagmus to those who had recovered as the light minimum diminished.

Dealing with light difference I found a similar condition. It was normal in 51 per cent and subnormal in 49 per cent, while the proportion of cases with signs or symptoms of nuer's nystagmus to those without them tended to increase more definitely than in the case of light minimum.

I am aware how inadequate these records are, both in numbers and in the manner in which they have been worked up but in spite of this I suggest that possibly there are some lessons to be learnt from them. The first is, unfortunately the negative one, that I have not found any evidence that examination of the light sense will help us in definitely deciding whether a man has recovered from miners' nystagmus. Another arises from a consideration of the possible causes of the symptom. At first sight it would seem to be obviously a part of the neurosis which is the true cause of most of the incapacity arising out of the disease, but it is possible that this may not be so in all, or even in the majority, of the cases. During the war Ransome Pickard and G. W. Lloyd* found that a number of men who were invalided suffered from a mild form of scurvy with night-blindness due to deficiency of vitamin from insufficient supply of vegetables, and had symptoms somewhat resembling those of miners' nystagmus, and Barton states that the blood of men suffering from the disease is deficient in haemoglobin, the average being 75 per cent of normal. It may seem a far-fetched theory that some of the prolonged cases of miners' nystagmus are really suffering from vitamin deficiency, but these men cannot be in a position to afford expensive food and it is possible that they may be using margarine, which is notoriously deficient in vitamin D. I throw out the suggestion as indicating a line on which investigations might be carried out with regard to the general condition of the sufferers from this most serious disease, on the lines suggested by Mr. Freeland Fergus, with some possibility of doing something for the patient. I cannot refrain from expressing my opinion that in spite of all the discussions which have taken place on miners' nystagmus, and all the money which has been spent on compensation and deciding whether individuals are entitled to it or not, the poor patient has been most shamefully neglected, and very little attention has been paid to his general condition or to the measure which ought to be adopted to improve it.

AN UNUSUAL CASE OF SELF-INFLICTED WOUNDS
THROUGH THE SKULL FOLLOWED

BY RECOVERY *

BY

JOSEPH J. LEVIN,

HONORARY SURGEON JOHANNESBURG GENERAL HOSPITAL, SENIOR
LECTURER IN CLINICAL SURGERY AND IN FORENSIC MEDICINE
UNIVERSITY OF THE WITWATERSRAND

On May 22nd, 1926, a European married woman, 27 years of age, was admitted to the gynaecological wards of the General Hospital, Johannesburg, under Dr Gibson, with a tentative diagnosis of salpingitis. At the laparotomy, which was performed on May 25th, both tubes were found to be inflamed and both ovaries cystic. There were dense adhesions in the pelvis. The appendix, which was long and slightly congested, was all that was removed.

On October 9th, 1927, this woman was admitted to the hospital again, under the care of Mr Ramsay Daly, with the head of a nail visible in the right temporal region of the scalp and an incised wound on the flexor aspect of her left wrist. She received immediate treatment from Dr Coetzee, house surgeon to Mr Daly, to whom I am indebted for the notes of the case at that time.

The history obtained from the woman, who was quite conscious although somewhat dazed, was that she had driven the nail into the right temporal region herself, with the back of a chopper. The exact situation of the puncture was one and three-quarter inches behind the right zygomatic process and three-quarters of an inch above the zygomatic arch. She had also cut her wrist with a pair of scissors, severing the flexor carpi radialis and the palmaris longus tendons. The head of the nail, with a quarter of an inch of its stem, was visible externally. The nail was removed with a pair of dental forceps, and was found to be three inches in length (see the shorter of

the two nails in the illustration). The wound was cleaned with ether, painted with iodine, and sealed with a collodion dressing. It healed by first intention and gave no further trouble. Under general anaesthesia the tendons of the wrist were sutured, the skin wound closed completely, and the patient was discharged on October 26th.

Dr Coetzee is of opinion that from the direction of the nail

when he extracted it the right temporal lobe of the brain must have been penetrated. He also remarks in his notes that there were no signs of gross mental aberration when she left the hospital.

On November 28th this same woman was admitted to the General Hospital suffering from signs and symptoms of gall bladder disease. On this occasion she was placed under my care. Her mentality at this time can best be described by saying that she was garrulous and silly, yet I could not definitely state that she was grossly mentally deranged. In other words, she required no special attention as regards her mental condition. I operated on her on the day of her admission, and found the gall bladder full of gall-stones. I removed the gall-bladder. She made an uninterrupted recovery, and was discharged on January 24th, 1928.

On March 23rd the woman was again admitted to the hospital under my care. On examination, at 4.15 p.m., I found the head of a nail six inches from the nasion and half an inch to the left of the middle line in the scalp. A skinogram showed a long nail right through the brain

(see illustration). She was conscious, and there were no signs of paralysis. She recognized me and addressed me by name. She gave a history of having driven the nail into her head with the back of a chopper. She asked me please to remove the nail as it was painful. There was an incised wound on the left wrist. No tendons had been cut. Under general anaesthesia I removed the nail, which

proved to be four inches in length (see the longer of the two nails in the illustration). I believe it to be the correct procedure in all punctured wounds of the skull and in all depressed fractures to trephine, and this is my usual practice. Therefore I proceeded to remove a button of bone around the punctured wound in the skull. I found that the inner table had been damaged very little more than the outer table of the skull. The dura

bulged into the wound on account of subdural haemorrhage, and no pulsation was observed. I opened the dura by a cruciform incision and evacuated a good deal of fresh blood clot, and when this had been removed there was still some oozing from the cavity. As I could not see where the haemorrhage was coming from I plugged the cavity in the brain which had been made by the effusion of blood, and left the end of the plug protruding through the skin incision. The skin flap was closed by silk-worm gut suture. Forty-eight hours after the operation I removed the plug, and as I did so there was an efflux of what I took to be slightly blood-stained cerebro-spinal fluid. The wound healed by first intention. On March 29th she exhibited a double Kernig's sign and her neck was a little stiff. A lumbar puncture was performed, and showed the cerebro-spinal fluid under pressure, but perfectly clear.

The report from the South African Institute for Medical Research on the cerebro-spinal fluid was as follows:

'Microscopic examination of this specimen showed the presence of an occasional polymorphonuclear leucocyte, lymphocyte, and Gram positive bacillus. Cultivation has resulted in a scanty growth of diphtheroid bacilli only.'

Physically the patient improved day by day, and there were no further signs of meningitis or any other complications, she deteriorated mentally, however. For example, one day she imagined that her right leg was shorter than the left, on another day she told me she was deaf, although she heard my whispered remarks to her, and on most days she wailed and cried on the slightest provocation. In addition to this I obtained from her husband the history that she had more than once tried to do away with herself. On one occasion she drank tincture of iodine, on another she tried to cut her throat. Moreover, he informed me that she had attempted to strangle her children. Taking all these things into consideration, I thought she would be safer in a mental hospital, so after she had been up and walking about the wards for some days I certified her and sent her to the Pretoria Mental Hospital on April 18th, 1928.

Dr Dorothy Holmes of the Pretoria Mental Hospital has kindly given me some notes about this patient's condition since her admission to that hospital, and also some notes of her condition when she was in the Mental Hospital as a voluntary patient in 1927.

'The patient was born in Ireland being the third eldest of a family of seven children. Her parents are both alive. Patient reached the seventh standard at school at the age of 14 years. She came to South Africa when she was 11 years old. Her girlhood was uneventful. Her home conditions were comfortable and happy

* Shown at the meeting of the Southern Transvaal Branch of the Medical Association of South Africa held in April 1928.

She worked as a typist earning £6 to £7 per month. Later she married and had two children. At the birth of the second infant the doctor advised that she should be sent to Valkenberg Mental Hospital. Her mother, however, would not agree to this and nursed her herself. The patient recovered and returned to her husband. This husband deserted her and she obtained a divorce from him in 1922. Her life with this man was very unhappy.

A year after her divorce she married her present husband who had been divorced from his first wife. His first wife is at present an inmate of the Pretoria Mental Hospital being mentally disordered suffering from manic-depressive psychosis of the mixed type. The patient has two children by the first husband living with her. On the advice of the probation officer in Johannesburg the patient applied for admission to the Pretoria Mental Hospital as a voluntary boarder on July 14th 1927. Previous to this she had become very sleepless her nerves were all upset, she stated that her husband gave her no money and no servants, that he ill-treated her and that she had to work very hard. She attempted to cut her throat with a razor.

On admission to the Mental Hospital in July she was depressed, unhappy and hysterical weeping readily. She conversed rationally and gave a correct account of herself. Her memory and orientation were intact. No delusions or hallucinations were elicited from her. She slept badly. By August 1st 1927 she showed some improvement was more cheerful and took an interest in her surroundings. She expressed herself as being quite better and wanted to return home. On August 9th 1927 she returned home.

It will be noted that on October 8th, 1927, she was admitted to the General Hospital, Johannesburg, after having driven the first nail into her head. Dr Holmes's notes on her condition on her second admission to the Mental Hospital, on April 19th 1928, are as follows:

The patient is acutely depressed, cries easily, and is oriented for time and place. She does not give a correct account of herself and feigns amnesia. She begins to speak and then says, "Oh! I can't remember my memory has completely gone." (Obviously not true.) She threatened suicide and emphatically told the nurse that she would do it properly next time. She is under constant observation. On May 1st the patient was still very depressed and looked miserable. She maintained that her memory was lost. She stated that she was lame but when she thought she was unobserved her gait and station were normal. She complained readily and was hypochondriacal. She slept badly and sedatives had to be administered.

By May 26th she had improved mentally and occupied her time by reading. She sleeps and eats well and desires to go home to her mother.

Her emotional tone is unstable but her consciousness is clear and her attention can be obtained and retained. Her behaviour is irresponsible. She converses rationally, but her reasoning and powers of judgement are slightly impaired. Her memory and orientation are intact. No delusions or hallucinations can be elicited. Her psychomotor reaction is slightly retarded.

Diagnosis: Manic-depressive psychosis—depressed type. **Prognosis:** (1) Immediate favourable (2) ultimate bad. Will recover from present attack but will probably relapse.

FURTHER OBSERVATIONS ON ADRENALINE MYDRIASIS AT THE MENOPAUSE

BY

JOHN H. HANNAN, M.A., M.D., B.Ch.M.

(From the Physiological Laboratories of the Middlesex Hospital.)

IN a preliminary communication to this Journal,¹ and elsewhere,^{2,3} I have presented evidence that women at the menopause show an increase in sensitiveness to adrenaline. It has been shown that no mydriasis occurs in normal individuals following the instillation of adrenaline into the conjunctival sac, whereas I have demonstrated that a transitory mydriasis occurs at the menopause in some women who complain of severe "flushing."

Our knowledge concerning the internal secretion of the ovaries has been considerably augmented by the work of Allen and Doisy and others working on the mode of action and methods of standardization of the oestrus-producing autacoid. Up to the present, however, the practical value of this work, particularly in connexion with the treatment of women with ovarian extracts has been somewhat doubtful, since the condition of oestrus, as such, does not occur in women, and the system of standardization based on the production of oestrus in lower animals is, therefore not strictly applicable to ovarian therapy in women. Furthermore it has been shown that there is more than one active substance present in the internal secretion of the whole ovary.

It will be seen that some investigation was necessary to determine if a symptom common to both man and to lower animals occurs following oophorectomy. Work was there-

fore undertaken to determine if adrenaline mydriasis following oophorectomy occurs in rats as it does in some women at the menopause.

EXPERIMENTAL TECHNIQUE

Test for Adrenaline Mydriasis

One drop of adrenaline hydrochloride was instilled into the animal's conjunctival sac, at five-minute intervals, for twenty minutes. The adrenaline mydriasis reaction was considered to be positive if the pupil on the treated side became obviously dilated within this time when compared with the untreated eye.

Over a period of twelve months a large number of young mature animals—rats, rabbits, and guinea-pigs—have been subjected to this test, but in no instance has mydriasis occurred.

On October 20th, 1927, 6 albino female rats having regular 3-4 day oestral cycles, were oophorectomized under ether. From this time until June 6th, 1928, the adrenaline mydriasis test has been applied at regular intervals to these animals, 64 individual observations having been made during this period. All the rats in this experiment showed adrenaline mydriasis commencing at different periods, in no instance did a rat which had once shown adrenaline mydriasis fail to reproduce the phenomenon at subsequent tests.

The reaction to adrenaline commenced in the animals under consideration on the 91st day of the experiment, and all rats showed mydriasis by the 154th day.

EFFECT OF ADMINISTRATION OF THE OESTRUS-PRODUCING AUTACOID

I have recently shown⁴ that the oestrus-producing autacoid is effective when administered in adequate doses by the oral route, and that it will produce changes characteristic of oestrus in the vaginal smears in test rats. The dose which is effective by the mouth is some sixty times larger than that which is effective when given subcutaneously. It was decided to treat the adrenaline sensitiveness of the rats by the oral administration of the autacoid, in doses of the size which had been found necessary to produce oestrus. Only 5 of the 6 rats were at this time available for the experiment, as one had been accidentally killed some time previously.

Experiment I—Twelve sows ovaries rich in follicles were given to the 5 rats in one cage. The adrenaline mydriasis test was applied on the third day of the experiment and was found to be positive in four instances, negative in one. An observation on the eighth day showed a return of the mydriatic reaction in all the rats.

Experiment II—Five hundred rat units of a tested preparation of the autacoid were mixed with the animals drinking water. On the third day of the experiment no adrenaline mydriasis occurred in any instance; a further observation on the eighth day showed a return in all instances of the mydriatic reaction.

Experiment III—In this experiment the number of rat units of the preparation administered in water was reduced to 150. Observations on the third and eighth days of the experiment showed adrenaline mydriasis in all instances.

DISCUSSION

It will be seen from these experiments that 500 rat units of the autacoid cured the adrenaline sensitiveness of all 5 rats, 12 sows' ovaries produced a cure in only one case, 150 rat units of the autacoid failed to produce any effect.

In my experiments on the production of oestrus similar doses of the autacoid and sows' ovaries were administered to litters of 6 rats, as compared with the batch of 5 animals used in this experiment, and it is interesting to note that the dosage of the autacoid which I had found necessary to produce oestrus corresponded roughly to that which was necessary to control mydriasis in the investigation under consideration. It will also be observed that the controlling influence of the autacoid passed off in all instances by the eighth day of the experiment.

In my work on women, to which I have drawn attention previously in this paper,⁵ only 6.2 per cent. of those women at the menopause who were tested showed adrenaline mydriasis whereas all the rats gave positive results.

In order to explain this phenomenon the point which first arises is that women suffering from the normal menopause have still some ovarian tissue left, and are but

suffering from a diminution in the amount of the internal secretion, whereas the rats had all ovarian tissue removed. If this were the explanation one would expect to find that normal menopause would not all show whereas all women suffering from a surgical menopause associated with total removal of the ovaries should show the reaction.

Dealing with the first point, an effort was made to obtain some rats of menopause age, and here considerable difficulty was experienced, and an interesting point arises which has an important bearing on claims which have been made in the rejuvenation of old animals. I have found that either old animals are pets, and are therefore not available for experimental work at any price, or, if they are not pets, for economic reasons are never allowed to grow old.

After considerable trouble, however, 6 rats, all guaranteed to be 2 years old or more, were obtained, but one of these has had a litter, 4 show oestrous cycles at regular intervals, and only one rat was found to have no oestrous cycles. It is interesting to find that this rat, which has a senile cataract in one eye, gives a constant mydriatic reaction.

With regard to the testing of women who have had all ovarian tissue removed, some difficulty has again been experienced owing to the reluctance with which most surgeons remove all ovarian tissue. Twelve women who have undergone Werthorn's radical operation for carcinoma of the cervix have been tested, however, and in only one instance was adrenaline mydriasis present. It is therefore obvious that some other explanation of the difference in the percentage of reaction between rats and women must be found. As I have shown elsewhere,¹ adrenaline mydriasis in women invariably passes off when the symptoms of "flushing" cease, and that not all women who suffer from "flushing" at the menopause show adrenaline mydriasis. I have advanced a hypothesis in this *Journal*² that the disturbance of the sympathetic nervous system, in particular the abnormal adrenaline effects, is but a temporary phenomenon consequent upon the withdrawal of part or whole of the internal secretion of the ovaries, and that the duration of the symptoms depends entirely upon the speed at which the compensatory activity of the general endocrine system occurs. It would seem, therefore, that this compensatory activity is much more rapid in women than in rats.

Finally, I would suggest that the experimental work which I have outlined in this paper justifies the following conclusions:

- 1 The adrenaline mydriasis phenomena associated with the menopause in women occur also in oophorectomized rats.
- 2 The adrenaline mydriasis reaction occurs with more regularity in rats than in women.
- 3 The oestrus-producing antacid can cause rats to lose the adrenaline mydriasis effect if administered in adequate doses.
- 4 The antacid is effective when administered by the oral route in doses corresponding to those necessary to produce oestrus.
- 5 Diminution in the amount of the oestrus-producing hormone is responsible for adrenaline mydriasis at the menopause, and, as this phenomenon is always associated with severe vasomotor phenomena in women, is also probably responsible for these symptoms of the menopause.
- 6 The oral administration of the oestrus-producing antacid is rational treatment for the vasomotor symptoms of the menopause.
- 7 The dose will have to be repeated within seven days if a permanent effect is required.
- 8 Though administration of the antacid at the menopause is rational treatment, the enormous doses required will prevent the maximum benefit from such treatment being attained until preparations of increased activity are available.

I wish to record my appreciation of the helpful criticism and advice which I have received from Professor Swalo Vincent and from Mr J H Thompson of this department.

CARDIOSPASM.

BY

H H GREENWOOD, B S LOND, F R C S LOND,
CONSULTING SURGEON TO THE O W R HOSPITAL, SWINDON

THE use of the term "achalasia" implies a pathology analogous to that of Hirschsprung's disease and of congenital hypertrophic stenosis of the pylorus, both these diseases are probably congenital in their origin, both are accompanied by demonstrable hypertrophy affecting the muscular coat of the alimentary tube, whereas in cardiospasm the condition is certainly not congenital, and the existence of any hypertrophy of the muscular coat remains a subject of contention.

The term "cardiospasm" has an established place in the literature, and clinical observation bears out its descriptive accuracy, it would seem that the term "achalasia" is a premature attempt at generalization, facile and tempting, but quite unjustified by the present state of our knowledge.

The opinions expressed in recent literature by eminent authorities¹ show a lack of unanimity as to the cause of the disease, nor is there general agreement about the counsel of perfection in treatment.^{2,3,4,5}

The symptoms, slowly progressive, fall roughly into three stages (1) Discomfort, not amounting to pain, in the epigastrium and behind the sternum (2) Precipitate vomiting, coming at intervals, later occurring at every meal, pain, sometimes severe, usually precedes the vomiting and is relieved by it (3) The vomiting becomes less precipitate. The oesophagus has become dilated so that it will hold a pint or more, the propulsive power of the oesophageal wall has weakened, and food enters the stomach mainly by hydrostatic pressure.

The disease usually occurs "in individuals of middle and late life" (Wright). The youngest case in the series recorded by Walton⁶ developed symptoms at 21 years of age, the average age of onset was 46 years. In a case sent to me by Dr Moore the age of onset was earlier—16½ years. The symptoms developed in the manner described above, there were, however, other features of an unusual character that are interesting.

The patient an unmarried man, now aged 25, became an apprentice at the age of 16 in an engineering works one and a half miles distant from his home. The long hours of hard physical labour and his rapid growth during the period of adolescence demanded abundant food. Half an hour's rapid uphill walk a similar period to return, left only a few minutes for a substantial meal at noon. In the evening, reaching home tired at 6 o'clock he had another hearty and hasty meal, hurrying to reach the technical college for evening classes at 7 o'clock. His teeth were very defective. In consequence all his meals were imperfectly masticated and were followed immediately by active exertion. The penalty of this constant bolting of food was the onset of symptoms of cardiospasm at the age of 16½ years. For several months the dilated oesophagus was emptied from time to time by vomiting, and relief from the pain followed. One day, after running rapidly up and down stairs, he discovered that the usual oppression in the chest and the sense of impending vomiting were suddenly relieved, and he felt something pass on into the stomach. He thereupon adopted the ingenious manoeuvre of springing up in the midst of a meal (when the symptoms invariably bad their inception) and jumping with a curious side-to-side action first on one leg and then on the other, until he felt a mass slide suddenly through an obstruction, he experienced an immediate freedom from pain, and he was able to resume his interrupted meal.

His general health began to suffer and he was obliged to abandon his employment at the works. He went abroad to Malaya, and there although now equipped with efficient dentures and no longer condemned to hurried meals the symptoms persisted unabated. During the last few years they have, indeed grown worse and he has slowly but steadily lost weight a stature of 6 ft 1 in consoled ill with a weight of 9 st 8 lb. Sometimes pain and oppression were such prominent and urgent features that vomiting would alone serve to relieve his distress. He consulted various medical men and ingenious explanations were offered but the cause was usually ascribed to nerves, an attribution probably influenced by his curious salutory movements.

Whilst on 'long leave' he was referred to me and I had several opportunities of seeing typical attacks during meals, ushered in by a growing expression of distress, and culminating in a sudden spring from his chair the execution of his curious jumping dance sometimes lasting a few minutes sometimes as long as fifteen minutes before sudden relief came, was very striking and suggested the existence of an oesophageal pouch or of cardiospasm.

A barium meal and x-ray examination by Dr Godfrey Mitchell (April 16th 1928) revealed clearly the typical appearances of an advanced case of cardiospasm (See Fig 1.) Since it was imperative that he should return to Malaya in about three months' time he wished to obtain a cure as nearly certain and as permanent as was attainable.

The various possible courses were outlined to him; he rejected as impracticable the tedious and uncertain dilatation by the repeated passage of bougies by Plummer's bag¹ or by the mercury tube so confidently recommended by Hurst.² Constrained by circumstance he elected to submit to the operation so ably and convincingly advocated by Walton.³ With his preference I concurred the more readily in that his father, a medical man, counselled this course. Where time and the tolerance of the patient are limited it is well to remember that Mitchell has recorded his having "seen patients who have passed the mercury tube 35 times a week without obtaining any permanent relief."

Accordingly on April 22nd 1928 under gas, oxygen and ether I opened the abdomen at Glenwood Nursing Home. He was very wasted, the chest long and narrow, the epigastric angle acute, the liver enlarged and low lying (possibly from the frequent attacks of malaria that he had endured), so that access to the stomach was rather difficult. Contamination of the rest of the abdomen was prevented by large gauze packs. The stomach was then opened on the anterior aspect by an incision in its long axis, the free bleeding from the edges being arrested by "mosquito" forceps and ligatures of fine catgut. The initial difficulty encountered was the finding of the cardiac orifice, but by patience this was located, a small tightly closed dumple-like opening resembling an anus spasmodically contracted by a fissura

enjoys an ordinary diet, and is steadily losing his emaciated appearance.

On July 2nd, 1928, Dr Godfrey Mitchell again x-rayed the patient, and reported as follows:

"Food now passes very much more freely into the stomach and even when thick paste was swallowed no large accumulation took place in the oesophagus. There is still some dilatation of the gullet but considerably less than at the time of the previous examination."

The x-ray appearances are seen in Fig 3. Although there is still some dilatation the tube of the gullet is seen to be flaccid, muscular tone is not yet regained, but there is no arrest of food. It is evident that any repetition of his former habit of swallowing large unmastered masses of food, which could not at once pass onward into the stomach, would assuredly cause recurrence of symptoms. Herein there possibly lies the explanation of the relapses that occur in a certain proportion of successful cases. In like manner the recurrence of gastric ulcer and the formation of jejunal ulcer some months or years after a gastrojejunostomy is more closely related to a reproduction of the same factors that caused the original lesion—oral sepsis, defective mastication, grossly unsuitable food, overindulgence in alcohol and tobacco—than to any inherent

FIG 1.—Antero-posterior view of dilated oesophagus April 16th 1928 before operation

FIG 2.—Oblique view of the same case April 16th, 1928 before operation

FIG 3.—Radiogram after barium meal, July 2nd 1928 after operation

in ano. The little finger, then the forefinger followed by the ring and middle fingers, were cautiously inserted until after about fifteen minutes the thumb too with the hand in the obstetric position gained admission.⁴ Stretching was cautiously continued until the opening became lax, the fingers then passed easily along the 1 inch of intra-abdominal oesophagus to the diaphragm where the aperture seemed slit-like and required less force to secure relaxation than did the true cardiac orifice.

Despite abstinence from food for the antecedent twenty-four hours the anticipated gush of dark green fluid flecked with fragments of undigested food followed the dilatation at least half a pint was mopped away and a similar quantity flowed later into the stomach whilst the gastric incision was being sutured, another 6 ounces were vomited seven hours later after which none was returned.

The period of moderate shock with intense pain in the left chest behind lasted twenty-four hours and would seem to be a sequel inseparable from any severe operation in a region so sensitive to trauma; however gentle the manipulations employed. A bronchitis, with shallow distressed breathing was not unexpected and happily subsided at the end of three days. During these three days nothing was given by the mouth, abundant fluid (with sodium bicarbonate and glucose) being supplied by the rectum. From that time onward the swallowing of fluids and later of solid food was painless.

Healing and recovery were uneventful, the complete disappearance of all symptoms being remarkable. None the less gratifying has been the steady increase in weight, so that three months from the date of the operation he weighed 10 st 9 lb, he now weighs over 11 st.

The symptoms in this case etched clearly the clinical picture of cardiospasm. The ingenious and effective manoeuvre of jumping in order to relieve the urgent sense of pain and oppression appears to be original.

The patient is now completely free from any symptoms.

* This description applies to a small hand taking a 61 glove.

defect in the operation, whose consequences would become apparent within a few weeks. It is always difficult to eradicate long-established habits whose evil tendency is not fully realized by the patient.

Hurst has denied the existence of spasm, and has assumed an exact parallel between cardiospasm and congenital pyloric stenosis. In the latter there is undoubtedly a hypertrophy of the circular muscle at the pylorus. One cannot but be impressed in doing Ramstedt's operation with the (relatively) enormous mass of muscle that needs division in an infant a few weeks old. Surely such a condition is either congenital or develops soon after birth, antecedent to and not caused by the spasm that gives rise to the symptoms of obstruction. It does not follow that the spasm has given rise to the hypertrophy. Nor does the absence of any hypertrophy of the circular fibres around the cardiac opening of the oesophagus negative the existence of a spasm seen and felt in a case which is clinically one of cardiospasm. After feeling with the finger the tightly closed cardiac orifice slowly then more rapidly, yield to pressure there can remain no doubt in the mind of the surgeon as to the presence of spasm.

A closer parallel is found in a fibrous stricture of the urethra on which has been superimposed a spasm that yields to persuasive measures. The absence of any demonstrable hypertrophy of the urethral sphincter does not invalidate a diagnosis of spasmodic stricture in the living subject.

Rake⁵ has carried a stage further our knowledge of the changes found *post mortem* in Auerbach's plexus. Whilst

admitting the reality of the lesions described, it is difficult to follow the process of reasoning which converts the degenerated nerve fibres of any share in the causation of the disease. If such a lesion were the true causative agent, or even one factor, by what magic do these cases recover so rapidly, so completely, and so permanently after the simple procedure of overstretching the constricting tissues?

Acute controversy has arisen as to the cause and pathology,^{12, 13, 15} in the course of which fact and fantasy have not always been clearly distinguished. Brown Kelly¹³ dissected two specimens and "demonstrated both muscular coats to be of uniform thickness and without any special aggregation of fibres at or near the cardia. These findings seem to admit of only one interpretation—namely, spasmodic contraction." They certainly prove that hypertrophy of the muscle forms no essential feature or a case of cardiospasm, and effectually preclude any analogy with hypotrophic stenosis or Hirschsprung's disease, in both of which muscular hypertrophy forms a prominent and invariable feature. This analogy has gained a certain amount of credence by a parrot-like repetition, unsupported by facts. Pure theory is admissible if it helps to formulate treatment, but such a theory as this one neither satisfies reason nor directs practice.

There is a parallel to be found in the dysphagia duo to spasm at the upper end of the gullet at the "post-crucoid" level.^{10, 11, 12} In the symptom-complex of "dysphagia with anaemia" described by Jones and Owen¹ pathological changes in the mucous membrane at the site of obstruction are stressed as a prominent part of the clinical picture. Again, Brown Kelly and Paterson¹⁶ give evidence that, in a goodly proportion of cases of spasm at the upper end of the gullet there have been observed fissures, erosions, bands or membranes, chronic glossitis, or early carcinoma. Sometimes no lesion of the canal is detected by the oesophagoscope,¹¹ but that does not negative their existence. Whether or no any lesion was found, all observers agree that the element of spasm was constant.

Wright¹ states, "It is an undoubted fact that spasm at the entrance of the oesophagus occurs in association with superficial fissures and erosions." Although I can find no record in any *post-mortem* reports of cases of cardiospasm in which fissures and erosions were found at or near the cardiac orifice, it is possible that these would not be distinguishable through the oesophagoscope, and may readily escape detection at the necropsy unless definitely looked for. In Sir St. Clair Thomson's case¹⁶ of cardiospasm he remarks on the presence of a profuse growth of *Oidium albicans* on the wall of the dilated oesophagus. Certainly the demonstration of cracks and erosions would yield a more illuminating pathological picture than does the mere presence of degenerated nerve fibres in Auerbach's plexus. The latter might be expected as a natural sequence, their existence has been demonstrated by Rake¹, that they are in any way the ultimate cause of cardiospasm is pure theory and extremely improbable.

Hurst¹² writes of "the accompanying oesophagitis in the earlier stages, before the degeneration of Auerbach's plexus is complete." Surely when the nerve plexus becomes completely degenerated there is an end to all hope of cure or even improvement by bougies, mercury tube, or operation. There is an ingenuousness about the statement that the mercury tube "closely approximates to what happens under natural conditions." The weight of the mercury tube is about the same as that of the column of food in the dilated oesophagus.¹⁴ It might be inferred from this that the mercury tube is no more potent as a curative agent than the 8 in. column of food.

In the published cases there is a dearth of information regarding the habits of the patients in the years antecedent to the onset of the disease. Consideration of the case detailed above suggests a simple and, I believe, an adequate explanation of the origin of the disease. The repeated hurried swallowing of large masses of imperfectly masticated food too large to pass at once through the cardiac orifice, so that they must remain for long periods in the lower oesophagus causes a mechanical dilatation of that tube. The oesophageal wall, insulted by unduly prolonged

contact with disintegrating food, yields grudgingly, the dilatation of the contiguous cardiac opening induces a reflex protective spasm.

Comments

1 In the case reported there was very definite powerful spasm. Doubts as to the existence of spasm have been expressed, but the "pathology of the living" is more convincing than any theoretical speculations, or even experiments, on the cadaver.

2 The degeneration of the nerve fibres in Auerbach's plexus is interesting, but not germane to the question of cause. If the integrity of the plexus is essential to proper function the immediate and complete recovery after the various forms of stretching postulates an immediate and complete recovery of the nerve lesions, which is obviously impossible.

3 The disease is an acquired one, not comparable with congenital conditions, such as Hirschsprung's disease or congenital hypertrophic stenosis of the pylorus. Therein lies the hope of permanent cure.

4 The early age of onset (16½ years) in the case recorded is of interest.

5 The curious saltatory gymnastics adopted to obtain relief do not appear to have been previously recorded.

6 The bolting of food was clearly the cause in this case, and will probably be found to be the main factor responsible in all cases.

7 Plummer with the help of his bag only claims 81 per cent of cures, and of these some relapse. Operation as advocated by Walton offers more certain, less tedious, and possibly more permanent cure.

8 Correction of faulty habits will go far to prevent relapse.

THE PREVENTION OF COMPLETE RUPTURE OF THE PERINEUM

BY

T. STRETHILL WRIGHT, M.A., M.D. Oxon.,
OKEHAMPTON DEVON

THE conduct of maternity cases by the general practitioner has recently been somewhat severely criticized by eminent gynaecologists, it is therefore with a certain amount of diffidence that I, one of the rank and file, venture to make this intrusion into the domain of obstetrics. My justification is that complete rupture of the perineum—the subject dealt with in this paper—is a disaster the importance of which can be scarcely exaggerated, and that I believe it to be preventable by the method of reinforcing the perineum presently to be described.

I do not propose to enter into the causes of severe perineal lacerations, nor need I stress the obvious dangers of impatient and violent intervention. There is, however, no doubt that from time to time cases will occur in which, in spite of every care, the perineum may be torn right into the rectum. In such cases after the tear has attained certain dimensions it is hopeless to expect the perineum to go on stretching—Nature has begun to take a short cut to secure the necessary room, and the line of least resistance will be followed until the orifice is big enough to let the head pass. Whether the necessary room will be secured

before the tear extends into the rectum is largely a matter of luck unless the obstetrician can take active steps to limit the damage.

I suggest that, if he can strengthen the weak spot in the circle and can ensure that the perineum shall tear so far and no farther, he may make it possible for the extra room still required to be obtained by the resumption of the ordinary process of stretching. Acting on this idea I have for the past seven or eight years practised perineorrhaphy as a preventive rather than a reparative measure.

At the first sign of the perineum giving way I reinforce it by putting in a series of sutures of silkworm gut—from three to five in number, according to the amount of room in each patient between the fourchette and the anal sphincter—starting at the level of the perineal tear and

proceeding from before backwards. The needle carrying each stitch is inserted about an inch to the left of the central line of the perineum, passes between the scalp of the foetus and the deep surface of the

FIG 1.—Showing sutures inserted and tied in loops which gradually become tighter as anus is approached.

FIG 2.—Showing birth of head, sutures are now taut, preventing any further splitting of perineum.

FIG 3.—Showing analogy of the loosened shoelace.

perineum, and is made to emerge again through the skin an inch to the right of the central line. By using a long needle and taking in a wide area on each side of the central line a good purchase for the sutures is secured.

Now comes the most important part—the tying of the stitches. The accoucheur has to decide in advance how far he is prepared to allow the perineum to split. The uppermost stitch is tied loosely enough to allow that amount of splitting but not sufficiently loose to allow more, the next stitch must be a little less loose, and so on until the last one just in front of the anus, is reached—this is tied firmly. We now have a sort of lattice work of sutures which may be compared to the laces of a shoe after they have been loosened to allow the foot to be withdrawn.

As the head advances the stitches become taut, if they have been properly tied they should take the strain more or less simultaneously. If the top stitch is too tightly tied it will cut through the perineal tissue until the strain is taken by the sutures below. No single stitch would avail to hold in check a severe rupture of the perineum, it is the combination of a number of sutures all taking the strain together that saves the situation.

Several colleagues of mine have objected that the stitches must inevitably cut through. I can only urge sceptics to try this method for themselves. They will be surprised to find how well the stitches hold. So far I have not encountered a case in which there has been any serious cutting through.

In tying the sutures I do not use reef knots for after the child is born the sutures have to be drawn tight to bring together the edges of the torn perineum. A double turn is sufficient* to fix the suture (already sticky from its passage through the perineal tissue) in the state of looseness temporarily desired, or it may be tied in a bow, which can be pulled apart later. Another alternative is to take a single turn and clamp the half-knot with pressure forceps.

Naturally the greatest care has to be taken to prevent too great and sudden a strain being put upon the now reinforced perineum. The use of midwifery forceps helps to control and steady the advance of the foetus's head. In occipito-anterior positions the forefinger should be inserted to steer the baby's eyes, nose, and mouth safely past the upper stitches. Taking this precaution I have never experienced any difficulty in preventing damage to the face.

After the birth of the placenta it only takes a moment to draw the series of loops tight and to bring into exact apposition again the edges of the perineal tear. The sutures below the tear, having served their purpose, are snipped with scissors and pulled out.

It seems hardly necessary to warn the accoucheur that the stitches should be inserted *between* the pains, and that the needle must not be put in too deep, I happen to know of a case in which the doctor, trying this method for the first time, anchored the baby's scalp to the perineum.

As regards the value of these experiments, I must confess that I have not had enough cases to dogmatize. Rupture of the perineum is fortunately a relatively rare complication. The procedure described above is, at any rate, harmless, if proper precautions against sepsis are

taken, and the favourable results which I have experienced in every case in which I have employed it during a number of years encourage me to think that even in the worst cases it may, if rightly used,

prevent a tear from extending through the internal sphincter into the rectum. I think I may claim for it that it limits the damage and acts as a brake.

The description of this method is published in the hope that others will take the opportunity of testing its value and improving the technique. Hitherto I have only tried interrupted sutures, very probably the use of a single continuous suture (following more exactly the analogy of the loosened shoelace) would be simpler and equally effective.

THE RELATIONSHIP OF PLASMA CHOLESTEROL AND BASAL METABOLISM

BY

J. ADDYMAN GARDNER, M.A.,

READER IN PHYSIOLOGICAL CHEMISTRY, UNIVERSITY OF LONDON

AND

HUGH GAINSBOROUGH, M.D., M.R.C.P.,

PHYSICIAN TO ST. GEORGE'S HOSPITAL

In a communication in 1922 Epstein and Lande¹ endeavoured to demonstrate the existence of an inverse relationship between the blood cholesterol and the basal metabolic rate. Such a correlation was suggested by the fact that in subacute and chronic parenchymatous nephritis the basal metabolism is subnormal while the blood cholesterol is increased above normal. Epstein believes that this disease is really a metabolic disorder involving a hypothyroidism, and that the renal manifestations are only a part of the picture.

In support of this thesis Epstein and Lande have determined the blood cholesterol and basal metabolism in a number of cases of hyperthyroidism, in which they maintain that the same inverse relationship of these two factors also holds good. Their figures, however, hardly warrant the conclusions they have drawn. The colourimetric method they used for estimating the total cholesterol of whole blood, as has been repeatedly proved,^{2,3} is open to serious objection but, perhaps, a more important criticism is the use of the total cholesterol of whole blood as a significant value. They ignore the fact that the total figure includes the cholesterol of the corpuscles, which is in the "free" form only, and which is remarkably constant in health and disease, and also the fact that the plasma cholesterol exists both in "free" and in combined form as ester. The ratio

* Since writing the above I have had a case in which the double turn was not sufficient to fix the suture as desired. The suture was subjected to a sudden and violent strain and began to slip and a reef knot had to be made to save the perineum. I should therefore in future prefer the third method as the safest—that is taking a single turn and clamping the half knot with pressure forceps.

				0.0819	0.1451		

of these two forms of cholesterol in the plasma is subject to almost unexplained variations, and from a metabolic point of view the two forms cannot be considered as so identical that they can be estimated and considered as one substance.

Furthermore, they explain such figures as do not quite fit in with their thesis by assuming that in longstanding cases of hyperthyroidism there can be an "exhaustion of lipid," an expression which is meaningless to us, and also that at the characteristic the blood cholesterol is apt to be raised, for neither of these assumptions is there any definite foundation. Luder⁴ also investigated, in a similar manner, a case of myxoedema, with and without thyroid administration,

and reported the same inverse relationship between blood cholesterol and basal metabolic rate.

Epstein's views as to the nature of subacute parenchymatous nephritis (so-called nephrosis) are now well known, and the many changes in the body metabolism in this condition have led to the increasing acceptance of the view that it is a metabolic disorder, the renal changes being secondary. His method of treatment by high protein feeding and thyroid administration is also based on this hypothesis. The results reported by Epstein and Lando are important as a basis for these theories, and we have thought it worth while to investigate the matter further.

Two types of patient were investigated: cases with hyperthyroidism, and cases with hypothyroidism, the latter type both during treatment with thyroid preparations and without such treatment. The basal metabolism was estimated, using a Douglas bag, according to the accepted method. The blood for analysis was taken immediately after the filling of the Douglas bag by the patient, when he was in a "fasting" condition—that is, he had had no food for fourteen hours. The plasma was separated, and the "free" and ester cholesterol estimated by the digitonin method, using the procedure which we have described in detail elsewhere.⁵

Before proceeding to discuss our results it is important to set out certain considerations. We have shown in a study of the cholesterol content of normal human plasma that the variations in cholesterol content are so considerable that an average figure for the normal plasma cholesterol is devoid of meaning, unless the normal limits of variations are taken into account.⁵ A single individual, however, tends to keep, in fasting state, a more or less constant level of cholesterol content of his plasma.⁶ Consequently it is by no means easy to demonstrate hypercholesterolaemia or hypocholesterolaemia of small degree, except, perhaps, for an individual the cholesterol content of whose plasma, under normal conditions, is known.

Furthermore, the level of the plasma cholesterol can be affected by feeding, and though this alteration is by no means necessarily in the sense of a hypercholesterolaemia—the change being sometimes in the opposite direction—this result of feeding should be avoided by examining whenever possible the plasma of subjects when in the "fasting" condition.⁶

RESULTS

In Table I we present the results of estimations in cases of exophthalmic goitre. In the case of one of the men and one of the women more than one investigation was made. These two cases are particularly interesting in that the plasma cholesterol shows wide variation bearing no relationship to the basal metabolic rate at the time of observation. Taken as a whole the cholesterol figures yield an average a little lower than we have found in normal

TABLE II.—Showing Results in Four Cases of Hypothyroidism

Case and Date	Basal Metabolic Rate	Respiratory Quotient	Percentage Cholesterol in Plasma.			Percentage of Total Cholesterol as Ester	Treatment

April 29	+10.2	1.09	0.0528	0.1167	0.1695	68.8	Thyroid omitted since April 29th
May 4	+10.8	0.97	0.0562	0.099	0.1661	62.2	Idio

individuals but nevertheless the figures are practically all within the normal limits of variation

It seems reasonable to conclude from our figures that, in cases where the basal metabolic rate is above the normal, an inverse relationship between the basal metabolism and the plasma cholesterol does not exist, either as regards free, or ester or total cholesterol

In Table II are given the results of the investigation of four cases of hypothyroidism, three being cases of myxoedema and one a cretin who had had thyroid treatment for twenty years. The most fully investigated case was that of I. B., who presented a classical picture of myxoedema. Here, definitely, the increase of basal metabolic rate called forth by the administration of thyroxin or of thyroid gland led to a lowering of the plasma cholesterol, most noticeably in the case of the ester cholesterol. G. D. gave a very similar result, but A. M. who was examined after administration of thyroid gland for a somewhat shorter period did not show the same effect. In the case of A. C. the estimations were first made while the patient was taking thyroid, a treatment he had been having regularly for twenty years. Thyroid administration was then omitted during the rest of the experiment. The alteration of cholesterol level is, in this case only of relatively small degree, and in an opposite direction from that suggested by hypothyroidism. However, this case is perhaps not entirely comparable with the cases of myxoedema for it is not certain that after such long-continued thyroid administration omission of this treatment would lead to a sharp effect

CONCLUSIONS

We do not find that cases of hyperthyroidism provide any support for Epstein's theory that the blood cholesterol is inversely proportional to the basal metabolic rate

As regards the cases of hypothyroidism there does appear to be some such relationship, and the cholesterol of the plasma is certainly above normal in the untreated cases of myxoedema

It is however, important to note that the hypercholesterolaemia shown in these cases of myxoedema does not reach the level of hypercholesterolaemia so frequently found in subacute parenchymatous nephritis, where the increase of plasma cholesterol is quite out of proportion to the lowering of the basal metabolic rate and this increase is often present in the later stages of the disease when the basal metabolic rate has become normal

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

A JAM JAR IN THE RECTUM

This case seems to be a surgical curiosity, and the clinical details may therefore be of general interest

A man aged 55, who was admitted to the Northern Hospital, Liverpool had suffered from a rectal prolapse for many years which recently had become difficult to reduce. He was advised by his friends to try to reduce it by pressure with the bottom of a half pound jam jar, and by some extraordinary mischance forced the jar up past the tuber ischi to the rectum. He attempted to remove the jar himself but failed and it was not until three days later that he visited his doctor. In the meanwhile the anal region had become very septic as the result of efforts at removal and pressure by the foreign body. His doctor having tried unsuccessfully to extract the jar sent the patient to hospital.

The house-surgeon made further attempts and found that the anus was so stretched that it was possible to remove a quantity of dirty rags which had been pushed into the open end of the jar which lay bare up. Even with anaesthesia and the use of all the available forceps and retractors it was impossible to extract it. I found that although the anus readily admitted the whole hand, and the jar was lying free above the tuber ischi on either side yet its diameter was just too wide to allow it to come through in any plane. Probably the explanation as

to how it had been introduced was that at the time there was no oedema or inflammation of the rectal wall, and it could then only just be forced past the tuber ischi. The patient described how once partially inserted the jar shot up into the rectum. As the anus and rectum were in an extremely septic and oedematous condition with some oozing of blood from small lacerations it was obvious that whatever else might be required a temporary colostomy was essential. The patient already under ether anaesthesia was prepared for an abdominal operation.

Through a median subumbilical incision the pelvic rectal junction was exposed. The gut wall was very congested and the jar was easily located in the upper rectum. The pelvic colon was examined with a view to ascertaining its mobility for the colostomy. An attempt to milk the jar down from above past the pelvic outlet failed, even with the aid of an assistant at the rectal end. It could not be manoeuvred past the ischial plane. After completely isolating the area with packs the jar was therefore extracted through a longitudinal incision in the lower pelvic colon and the opening was closed transversely. Flapine was applied and a corrugated rubber strip was placed close to the suture line for drainage purposes. A left inguinal colostomy was performed over a glass rod and the incisions were closed. The jar measured 24 in. in diameter at base and was 3 in. in height. The colostomy was opened in forty-eight hours and the lower colon and rectum were treated with lavage from above using hypertonic saline at first and later normal saline.

In three weeks time the rectal condition had returned to the normal and the external sphincter also had regained excellent tone. As there had been severe inflammatory reaction in the rectal and perirectal tissues and consequent fibrosis the probable result would be the cure of the prolapse. An intraperitoneal plastic operation was performed a month and a half later to close the colostomy, the spur having been previously more or less obliterated with a Paul's enterotome.

The colostomy wound healed satisfactorily and the patient was discharged as cured. The rectal prolapse has not recurred and the bowels act normally.

PHILIP HAWE, Ch M., F.R.C.S. Eng

AN EXTERNAL TERATOMA

The accompanying photograph of an anatomical curiosity, the like of which is, fortunately, rarely seen, may be of interest.

The body is that of a full-time European female infant born on September 19th at 6.10 p.m. The child, which was well nourished, gave out one or two gasping breaths and expired.

From below the left mamma there protruded an arm and shoulder, fully formed and developed. On examination a clavicle and part of a scapula could be felt. The arm and hand were perfectly normal in every respect, and the joints were articular. The left forearm of the body was composed of two radii and two ulnae with the hands complete. These two forearms were fused on their anterior surfaces. The humerus, although thicker in girth than

normal, was only single. The digits of this double hand were perfectly formed and tipped with nails. Lying laterally to the extra arm and shoulder below the left mamma was a cauliflower-like mass resembling two ears joined by their lobes. There was also a piece of tissue resembling a penis, but not penetrated by a urethra. Next to this was the heart lying uncovered by pericardium and pulsating rhythmically. The left foot was everted in the position of talipes equinovarus.

The body weighed 8½ lb. and was well developed and nourished. The fusion of the two bodies does not seem to have impaired the development of either despite the rather cramped quarters.

Unfortunately I was unable to persuade the parents to allow me to do a dissection.

CLINICAL AND SCIENTIFIC PROCEEDINGS

ULSTER BRANCH NORTH-EAST DIVISION

The "Acute Abdomen" from the General Practitioner's Point of View

At a meeting of the North-East Division of the Ulster Branch on October 5th, the chairman, Mr D Huxy, read a paper entitled "The acute abdomen from the general practitioner's point of view."

Mr Huxy said that he proposed to differentiate all the affections in the abdomen and pelvis which were likely to be mistaken for one another. Better understanding of the transference of pain which often occurred in the acute abdomen would be obtained by recalling the nerve supply of the abdomen and pelvis. The skin of the anterior abdominal wall was supplied by the lower six thoracic nerves and the first lumbar. The ilio-hypogastric and the ilio-inguinal branches of the lumbar nerve supplied the hypogastric region, the skin over the pubes the inner aspect of the thigh, and the upper part of the scrotum. The tenth thoracic supplied the skin in the region of the umbilicus. These nerves ran obliquely around the chest. The eighth intercostal was placed posteriorly at the inferior angle of the scapula, anteriorly it ended midway between the xiphoid process and the umbilicus. The skin of the posterior abdominal wall was supplied by the posterior divisions of the same nerves. The anterior divisions of the first and second lumbar nerves, with the lower thoracic nerves, were connected with the corresponding ganglia of the sympathetic, with both white and grey rami communicantes. The nerve supply of the abdominal viscera was derived from the lower six thoracic and the first lumbar segments, and afferent impulses from the viscera reached the same segments of the spinal medulla, as did the afferent impulses from the skin of the abdominal wall. In pathological affections the afferent impulses from the viscera might become so altered in character as to overflow those cells for which they were originally intended, and stimulate neighbouring cells which were accustomed to receive impulses from the skin of the abdominal wall. When the stimuli of these latter cells reached the brain they were interpreted as painful sensations of the skin area supplied by the segments of the spinal cord involved. Pain of this variety, which might be felt in a different region from the viscus at fault, is spoken of as referred pain, and the whole reflex is called the viscerosensory reflex of Mackenzie.

The term "acute abdomen" implied uncertainty as to exact diagnosis, and appendicitis was the most prominent cause that produced the acute abdomen. In seven cases out of ten of pain in the abdomen, with some temperature and a history of vomiting, the correct diagnosis would be appendicitis, but other conditions had to be remembered. Mr Huxy cited the case of an old woman, aged 72, who had been ill for several days, she had a temperature and a marked swelling in the right iliac fossa, under an anaesthetic it was easy to see that it was not an appendix case, since the swelling came over to a central position, it was traced up the abdomen, and eventually found to be a twisted gall bladder containing about half a pint of fluid and ten or a dozen twists in the neck of the gall-bladder, which was becoming gangrenous. Complete recovery followed removal.

It was necessary to diagnose appendicitis from gastrointestinal catarrh, in which there were severe cramp-like abdominal pains, with vomiting, but the pain and tenderness were situated above the umbilicus and remained so, and the tenderness was only present during a spasm. There was no fever or tenderness, and the pain was rather relieved by pressure, the muscles were not rigid between the spasms. In a perforated gastric or duodenal ulcer the onset was more abrupt, the pain more intense, and the rigidity of the muscles was most marked in the upper part of the abdomen above the umbilicus. In perforation of a duodenal ulcer the rigidity often extended down to the right iliac fossa, simulating appendicitis very closely. In

children certain conditions might simulate appendicitis: pneumonia of the right base, diaphragmatic pleurisy, an acute *Bacillus coli* affection of the pelvis of the kidney, and acidosis with a temperature and constipation. In some cases of appendicitis the pain and tenderness were not in the right iliac fossa, because the appendix had not come down to its usual situation, but remained close against the liver and in front of the right kidney. Such a case was very like a perforated duodenal ulcer, but the patient did not have the intense look of suffering as after a perforation, nor the boarded muscles, and the pulse was much better. In the end exploration was necessary. In acute cases of this kind cholecystitis, cholelithiasis, and renal colic had to be remembered. In gall stone colic there was intense vomiting when the pain was severe, the pain radiated round the right side, and perhaps over on to the left side or on the tip of the right shoulder. The site of greatest tenderness was below the tip of the ninth rib and half-way to the umbilicus. Cholecystitis could be distinguished from acute appendicitis by the site of the tenderness. In children with acidosis or pyelitis it was sometimes difficult to decide, but the abdomen was not rigid and moved freely on respiration. Diaphragmatic pleurisy and pneumonia were recognized by the sudden onset of pain and shivering, and pneumonia by the high temperature, the referred pain in the upper part of the abdomen, and the usual auscultatory sounds—crepitous sounds in pneumonia and friction sounds in pleurisy.

In perforated duodenal ulcer—another cause of an acute abdomen—the onset was sudden, the pain intense, and the abdomen was boarded and firm, not moving on respiration, there was usually a history of a good appetite, with heartburn and acid coming up in mouthfuls, severe pain at night awakened the patient, and was relieved by food. The only thing likely to be mistaken for it was a perforated gastric ulcer, but in this there was usually pain and vomiting shortly after taking food, and relieved by alkalis. In both cases an operation was required. If a perforated gastric ulcer on the anterior wall was properly treated it gave no trouble in the future. There was sharp pain and localized swelling, but none of the usual urgent symptoms, the ulcer had perforated, but was walled round by adhesions. Mr Huxy had seen several of these cases which recovered. In young girls with gastric ulcer there was sometimes intense pain simulating perforation which ended in a few hours, the etiology was unknown. Acute intussusception was a common cause of an acute abdomen in children, boys being more often affected than girls. The attack began as colic, causing the child to scream and draw up the knees and become pale, the eyes were widely dilated, and the pain was usually followed by vomiting. A normal motion might be passed, followed by violent tenesmus and a considerable quantity of mucus and blood being expelled at frequent intervals. On palpating the abdomen it was noticed that the right iliac fossa was empty, and there was a sausage-shaped swelling in the abdomen, with its convexity towards the umbilicus, this was caused by the mesentery dragging the tumour into a horseshoe shape. There was no rigidity of the muscles unless a spasm was present, and no temperature until inflammation set in. Acute colitis was the only disease likely to be confounded with intussusception, and ought to be easily excluded. Volvulus of the colon occurred in men between 40 and 60 years of age who were constipated. The onset was usually sudden, and there was complete obstruction with severe pain of a colicky character generally referred to the region of the umbilicus, tenderness in the left iliac fossa, and severe tenesmus. The most striking and characteristic sign was the early and extreme distension of the abdomen. As the seat of the lesion was low down in the abdomen vomiting was seldom an early or prominent symptom, the left side of the abdomen became prominent, and yielded a drum-like note.

Cholecystitis and cholelithiasis were frequent causes of an acute abdomen. The clinical signs of cholecystitis varied considerably, according as gall stones, if present, were situated in the gall-bladder, the cystic duct or the common bile duct, and were or were not associated with suppuration. The usual signs of indigestion might be accompanied by feelings of chilliness and attacks of violent pain, high

temperature, vomiting, and nausea. All forms of gall-bladder disease were common in stout plethoric women past middle life, many had borne children, and in many cases the earliest symptoms occurred during pregnancy, when the bile had a higher cholesterol content, favouring the deposit of concretions. The patients might otherwise be healthy and energetic. Men were less often affected. The acute recurrent non-suppurative form, associated with biliary colic, was the one likely to produce an acute abdomen; there was an acute attack of pain, with vomiting and prostration. The pain came on without warning and was agonizing, of a twisting colicky character, being most severe in the epigastrium, it radiated to the right shoulder and side, spreading over the ribs and back between the shoulders. In a certain proportion of cases there was severe pain over the deltoid. There was hyperalgesia of the skin over the painful area, and the abdominal muscles, especially the rectus, were rigid, the attack was followed by considerable shock, the pulse was fast and full, the temperature raised by a few degrees, and the breathing was rapid and shallow. The absence of rigidity did not exclude gall stones. Biliary colic was distinguished from renal, appendicular, and intestinal colic by the history of the prodromal stage, the location and radiation of the pain, the site of tenderness on pressure, and the absence of urinary symptoms.

In acute pancreatitis the illness started suddenly, and was not easily differentiated. There was usually a history of indigestion with cramps in the stomach, attended with colic and vomiting, or symptoms suggesting cholecystitis or duodenal or gastric ulcer. The initial pain was agonizing, and was referred to the epigastrium and upper part of the abdomen, marked epigastric tenderness was a constant symptom, vomiting of bilious matter was present, and might be so severe as to suggest an acute obstruction of the upper part of the small intestine. The vomit was never stercoraceous. The most reliable diagnostic signs were the localized tenderness across the epigastrium and a resistant mass in the situation of the pancreas. The pain in acute pancreatitis was felt across the back as well as in the epigastrium, and might be colicky, the vomiting was repeated with eructations of gas, and the rigidity in the early stages was not nearly so marked as in a perforation of an ulcer. As a rule the majority of cases of acute pancreatitis came to the operator as a disagreeable surprise. On opening the abdomen the existence of an acute pancreatitis was recognized by the presence of fatty necrosis in the shape of flat golden yellow patches scattered through the mesentery and the pancreas was found to be enlarged, with an effusion in the lesser sac of the peritoneum. In embolism and thrombosis of the mesenteric blood vessels the symptoms indicated an acute obstruction of a paralytic type, diagnosis was rare before the abdomen was opened. After obstruction, passing on to diarrhoea and the loss of large quantities of blood, the bowel became gangrenous and peritonitis started. Inflamed tuberculous glands in the right iliac fossa gave rise to an acute abdomen, with tenderness but little rigidity, the pulse and temperature were better, but the diagnosis was rarely made before operation. Acute prehlitis might be mistaken for an appendicitis before examination of the urine. Nephritis, colic, and stone in the ureter could usually be diagnosed by ordinary clinical methods and an x-ray examination.

Torsion of an ovarian tumour had been found to occur in 2 per cent of the cases brought to operation; the extent varied. The effect produced by twisting the pedicle was congestion, and, if the tension was tight, necrosis. Detachment might occur from a twisted pedicle atrophying and the tumour forming fresh connections. Rupture of an ectopic gestation might cause an acute abdomen, with severe abdominal pain, sudden in onset, and situated in one or both iliac regions. This was often followed by vomiting, and occasionally by diarrhoea, which might confuse the diagnosis. Commonly there was faintness and less often actual loss of consciousness from syncope upon these symptoms there supervened in the case of severe bleeding the signs and symptoms of concealed haemorrhage with usually slight haemorrhage from the uterus. When the loss of blood was spread over several days these symptoms were less severe, and pallor with a quick pulse might alone be

present. In a ruptured tubal pregnancy the occurrence of severe bleeding internally would be very evident, a recent history of a short period of amenorrhoea giving place to slight uterine bleeding would suggest ectopic pregnancy. Pelvic examination might show softening of the cervix and a swelling behind or to one side of the uterus representing the gravid tube. The space behind the cervix was full and had no palpable outline, being soft and doughy when pushed up with the finger. The fluid was not inflammatory, as there was a complete absence of tension; it was not a cyst, as the line was impalpable. In fulminating appendicitis the symptoms were mainly a profound toxæmia, and resembled shock more than tubal rupture. Uterine bleeding was not met with in appendicitis, but was almost always present in extrauterine pregnancy. The more common forms of appendicitis were easily distinguished from a severe internal bleeding. In perforation of a viscus the prominent symptoms were shock, followed by signs of an acute abdomen, and later by peritonitis. The general indications of pregnancy and of uterine bleeding were absent.

Pelvic hæmatocele was usually, but by no means always, due to ectopic pregnancy; it might be caused by rupture of a blood cyst of the ovary or of a tubo-ovarian hæmatocele. The diagnosis from a retroverted gravid uterus was not easy, but was very important, since treatment for the retroverted gravid uterus might spell disaster in a hæmatocele. The history usually presented well-marked differences: retention and incontinence of urine were present when the retroverted uterus was large enough to fill the pelvis, it was exceptional in hæmatocele. Bleeding from the uterus might occur with either, but the discharge of decidual tissue, apart from abortion, was only encountered in extrauterine cases. Attacks of abdominal pain strongly favoured the diagnosis of uterine pregnancy. On bimanual examination the gravid uterus was more uniform than a hæmatocele, and might sometimes be felt to undergo intermittent contractions. The point of chief diagnostic importance was that in a hæmatocele the body of the uterus was always found in front of the swelling which fills the pouch of Douglas. An ovarian cyst becoming incarcerated by adhesions in the pouch of Douglas and large enough to fill the pelvic cavity, gave the same displacement to the uterus as a hæmatocele. The swelling in the case of a cyst was more uniform and tense, the general outline was better defined, there was no softening of the cervix, and no irregular bleeding. Inflammatory effusions into the pouch of Douglas and inflammatory enlargements of the Fallopian tubes could best be distinguished by a careful consideration of the history, fever was common in inflammation at the beginning, but it was several days before it occurred in hæmatocele. In inflammation there was no pallor, the pulse, though quick, was of high tension and the general condition of the patient did not suggest hæmorrhage; the local tenderness in inflammation was much greater than in hæmatocele.

In the case of incomplete abortion the diagnostic error usually consisted in regarding a case of hæmatocele as an abortion, and in many cases the uterus had been explored and emptied before the true nature of the condition had been recognized. The mistake might be followed by serious consequences if the hæmatocele was ruptured or if septic infection occurred. Both were attended by the general signs of pregnancy, abdominal pain, bleeding from the uterus, and discharge of a membrane from the uterus, the cervix was found to be softened and on a perfunctory examination a peritubal hæmatocele might be mistaken for the body of the gravid uterus. The only safe rule was great care in examination of the position of the swelling, its correspondence in size with the presumptive period of pregnancy, the severity of the uterine hæmorrhage (which was hardly ever profuse in hæmatocele, but frequently was so in abortion) and the nature of the discharged tissue. Chorionic tissue being readily recognized by the naked eye. Acute cases of salpingitis might develop rapidly, grave symptoms such as occurred in other forms of the acute abdomen without any localizing signs being discovered in the pelvis. The main symptoms were fever and pain, vomiting except for the first few hours, was rare. The fever was usually severe and might be associated at the

beginning with chilliness or a rigor, thereafter the temperature ran an irregular course like septicæmia. In some cases the fever subsided rapidly, and in a few days might be normal, thus indicating that the inflammatory focus had been limited by adhesions. In other cases there might be exacerbations, with high fever, when fresh tissue was involved. The pulse rate was usually in proportion to the temperature, if the pulse rate was disproportionately rapid general infection was probably occurring. Abdominal pain and distension were usual in the hypogastric zone, they were in a special sense indications of peritonitis. There was great tenderness on pressure, and micturition and defæcation might be painful. The general condition of the patient was good, a high and increasing leucocyte count obtained on several occasions was the clearest indication of active suppuration. The swelling formed by the inflamed adnexa almost invariably lay in the posterior compartment of the pelvic cavity, as a rule not mesial, but posterolateral in position. In 75 per cent of cases both sides were involved. The rectal bimanual examination should always be practised, for it would show the close relation of the swelling, if large, to the anterior rectal wall. A general anaesthetic in cases where there was much tenderness was often indispensable.

Reports of Societies.

TREATMENT OF CONDITIONS CONDUCTIVE TO MENTAL DISTURBANCE

At a meeting of the Section of Psychiatry of the Royal Society of Medicine on November 13th the President, Sir MAURICE CRAIG, delivered his address from the chair, his subject being "A survey of some conditions conducive to mental disturbance, with suggestions as to their treatment."

Sir Maurice Craig said that fifteen years' residence in a mental hospital had inspired within him a desire to approach psychological medicine from the preventive side. He agreed whole-heartedly with those who believed that much mental disorder was preventable. The fatalistic attitude of the public towards the subject was pathetic, the apathy of the medical profession was more difficult to understand. Scientists to-day professed to investigate the sequence of phenomena, and recoiled from an expression of opinion as to why they succeeded each other. Thus, years ago experimental medicine aimed at the discovery of causes, now it was concerned with sequences. Certain clinical sequences had impressed themselves on his mind, both because of their frequency and because, in a given instance, the order of symptoms was predictable. If the principle that inherited tendencies largely determined the danger areas in any given man was accepted it became necessary to find what stresses might so reinforce these tendencies as to make them operative. For many years he had regarded hypersensitivity, with which a weak inhibition or lessened control was frequently associated, as one of the most important potential factors in the production of mental disorder. The threshold of minimal sensitivity differed in individuals, some children from their earliest years reacting unduly to weak stimuli, others acquiring extreme sensitivity later in life. If such undue sensitivity occurred in a person with neuropathic inheritance other changes commonly followed as sequences to the primary sensitivity. These changes might at first be either physical or mental, but the latter were followed inevitably by bodily changes. Disturbed emotion was so common a sequence to hypersensitivity that this condition had to be treated before the emotions became involved. On this assumption he had for over twenty years made a practice of keeping certain types of children continuously on small doses of bromide. To children under the age of 4 he gave 2½ grains of potassium bromide, to those over 4 twice that amount once a day. Under this treatment children who, owing to their over-reaction to stimuli, had been almost uneducable, became quiet and teachable, others less hypersensitive were helped in varying ways. He had noted that children who had been taking these doses of bromide for long periods and then had ceased to take them, slowly regressed, their

excitability sometimes increasing until epileptic fits occurred. To control the initial hypersensitivity he had further advised certain nervous types of men and women going out to the tropics, and certain active types at home to take 5 grains of potassium bromide daily, and in these cases also the results were equally beneficial. Pavlov's work appeared to confirm and explain these clinical observations. In excitable dogs the inhibitory function of the cortical elements was weak, yet following the administration of bromides there was no diminution in the magnitude of the positive reflexes, these, on the contrary, were extremely constant. Bromides, Pavlov concluded, were to be regarded not as sedatives, but as drugs regulating the activity of the nervous system by strengthening the intensity of internal inhibition. His own experience, said Sir Maurice Craig, coincided with Pavlov's observations, for small doses of bromide taken daily even for many years, far from dulling, appeared to increase mental capacity, no doubt by preventing wastage. Bromide in larger doses could be an extremely toxic drug, but if its action was to strengthen a weak inhibition, then the smaller the dose that would produce the desired effect the better.

Much mental disorder, he continued, was due to weakening of the inhibition, and not to any positive condition. Though certain malignant disturbances of the mind ran a definite course, and were classifiable under recognized names, there was a much larger group, embracing the exhaustion and intoxication types, different in character and far more accessible to treatment. Once the inhibitory function of the cortical elements had become weakened, the next steps downward were almost constant. The emotions became involved, and preoccupation, false reasoning, and ultimately failure of adaptation to environment followed in turn. All these could not occur without equally important changes on the physical side. The gastro-intestinal, cardio-vascular, and genito-urinary systems might all become affected, and the defensive mechanism of the vegetative nervous system might give rise to a disturbed endocrine balance, with the result that the physician, seeing the patient for the first time after these had progressed, might find it difficult to decide what was the initial cause of the mischief. Year by year he became more convinced that the changes in the vegetative nervous system were usually secondary, though, once established, they might have an important bearing on the illness. Experience had convinced him that the psychologist could not ignore the physical aspect in a case any more than a man who leaned towards the somatic aspect could neglect the psychical. The important matter in a lifetime sufferer from phobia was not the phobia, but the condition which permitted it to become effective. Much benefit might accrue from foretelling to the patient the course that his false reasoning would take him, or, if his outlook was already distorted, much good might result from going back as far as possible to the beginnings, and pointing out how the error of reasoning arose, and how in turn it had brought about a failure of adaptation to environment.

Passing to the question of sleeplessness—a symptom the importance of which had been increasingly impressed upon him, so that for fifteen years he had given it priority of place over all others—Sir Maurice Craig said that it was sometimes argued that sleeplessness had no apparent bad effect, but he was not convinced by the evidence for this view. It had also been said that it was the psychical effect of sleeplessness which was important, and this was true up to a point, but animals deteriorated and died when deprived of sleep, and this could not be due to psychological disturbances. Moreover, young children who did not sleep deteriorated more rapidly than adults. Before turning to the therapeutic aspect of the subject, it was helpful once again to consider Pavlov's observations. The dogs employed in his experiments had either an excessive or moderate tendency to excitation, or an excessive or moderate tendency to inhibition. Two different types of neurosis were thus produced, in the one group of dogs by the extreme weakening of the inhibitory function of the cortex, in the other by affecting the excitation of the corresponding cells. Both types of neurosis tended to persist even after a break in the experiment. Bromide produced rapid recovery in dogs with weak inhibition, but

no therapeutic measures were found to help the other variety, though these recovered spontaneously when left alone for a long time. These experiments, suggested Sir Maurice Craig might in the course of time help to explain the different types of nervous instability. For example, hypnotic drugs seemed almost to increase the excitement in certain maniacal states, though patients suffering from these *mania* states, if left alone, might spontaneously recover, but sleeplessness in patients corresponding to Parlor's former type was quickly corrected by suitable therapy, especially if this was taken early. The prescription of sedatives in sleeplessness was still a matter of controversy. All would agree that morphine, heroin, or opium should never be given for ordinary sleeplessness. With ordinary hypnotics, however, pleasurable sensations did not occur, and considering the number of persons for whom sedatives were prescribed it had to be admitted that addiction was very rare. The term "addict" should not be applied to the person who, under medical advice, took a sedative every night. The term "sleeping draught" was also used loosely and generally incorrectly. Most of the sedatives and narcotics did not produce sleep in the strict sense of the word. The barbitone group given in therapeutic doses by day induced no desire for sleep. It was also suggested by some that the sleep following the administration of any sedative was artificial sleep, and this was certainly not the case. He thought that drugs of the barbitone group might act, not as sedatives, but by protecting the weakened inhibition, and the prolonged use of this group was therefore invaluable in preserving the mental stability of certain types of persons. There was no evidence that the taking of drugs of the barbitone group for long periods was damaging to physical life. Many patients he had known who took dial or medinal continuously were professional and business men, representing every form of mental activity. In a very different class were patients suffering from a maniacal-depressive type of mental disturbance. He had kept four patients of this type on 5 grains of medinal daily throughout the period that they were well, in seven years two of these had not broken down at all, and two, though they had phases of mild excitement and depression, had had no attack comparable to those attending the taking of medinal. Finally there was the question of persistent sleeplessness in children: such sleeplessness was followed by mental and physical deterioration. For younger children he had prescribed 5 grains of potassium bromide, if necessary with 5 grains of chloral hydrate, every night for a long period, with excellent results, for children over 12 one tablet of dial or 5 grains of medinal was very helpful. If treatment was continued for eighteen months or more these children reached a very high standard of health but when the medinal or dial was stopped he continued to prescribe a small dose of potassium bromide each day. Mental breakdown in early life was a serious matter, leaving a tendency to further attacks between the ages of 16 and 20 and again during later years. Short treatment did not prevent these relapses, whereas the prolonged treatment just indicated did. The writer of the leading article on sleep and its disorders in the *British Medical Journal* of August 11th, 1928, had aptly and correctly summed up the clinical position when he said, "It need hardly be said, indeed, that we do not treat insomnia, but an individual who cannot sleep."

Dealing with the prevention of emotional and mental disturbances sometimes associated with surgical operation, Sir Maurice Craig emphasized the value of administering sufficient quantities of paraldehyde to apprehensive patients, in addition to the usual small quantities of morphine. This procedure induced such sound sleep that often the patients were unaware of being put under the anaesthetic. Repeated immediately after the operation, a dose of paraldehyde enabled the patient to sleep for so many hours that by the time he woke all severe pain had usually disappeared and mental trauma was thus averted. Medinal, dial, and allonal for some weeks before and several weeks after an operation also helped to make convalescence more rapid and more complete. Sir Maurice Craig suggested in conclusion that those who were seeking to prevent mental disorder had to seek out and correct

conditions which from clinical experience would appear to be fundamental in bringing about these disorders. The theory of a weakened inhibition appeared to him to explain so much. It defined the influence of inheritance, it explained why certain brilliant persons broke down, and why their normal mental activity only became involved as sleep and other bodily functions were affected, it explained the effect of toxæmias on the nervous system of certain individuals, or of surgical operation on others, it suggested why some persons broke down from over-stimulation or with advancing years it indicated to what end any treatment should be directed and why some persons relapsed when certain treatment was discontinued. This theory appeared to fit better than any other with his clinical and therapeutic experience and he believed that research from this standpoint would add much to our knowledge of the prevention and treatment of functional nervous disorder.

URINARY INFECTIONS AFTER RECTAL EXCISION

At a meeting of the Subsection of Proctology of the Royal Society of Medicine on November 14th, Dr CURTIS DUKES opened a discussion on urinary infections after excision of the rectum.

Dr Dukes described how, in a series of 50 cases of excision of the rectum (14 women and 36 men), the frequent cause and prevention of urinary infections had been investigated by daily quantitative tests for pyuria and repeated bacteriological examinations of the urine. Pyuria appeared on the sixth to the eighth day in all the women patients and in the 14 men patients in whom the retained catheter was sealed by a wooden peg. In some cases the pus disappeared in four to five weeks, but in the majority pyuria continued for several weeks. For two or three days before the flow of pus began staphylococci were recovered in pure culture from the urine, but later cultures usually showed a mixed growth of coliform bacilli and cocci. The lesion in the women patients and majority of the men was a cystitis, but in a few of the men patients it was possible that the pus might have been due to a severe proctitis. During convalescence from excision of the rectum urinary infections rarely produced obstructive symptoms and the presence or absence of an infection could only be determined by regular microscopic examinations for pus. Post-operative urinary infections were not due to the operation itself but to the means used for draining the bladder. In men patients the commonest source of infection was the wooden peg used for closing the retained catheter: the substitution of a better seal in the last 22 instances resulted in the prevention of infection of the bladder urine in two-thirds of the cases. When these methods of protection failed the subsequent infection ran a different course from that described for peg infections. The primary focus and manner of spread of these delayed infections had not yet been determined. In women the prevention of infection was a more difficult problem because of the danger of contact between the catheter and local septic foci. Dr Dukes said that the prevention of urinary infections after excision of the rectum was a task which demanded the close co-operation of the surgeon and pathologist. Regular microscopic examinations of the urine for pus were necessary, six tests at weekly intervals being the minimum for settling whether or not infection had occurred and revealing it at an early stage. To prevent infection of the bladder urine the end of the retained catheter must be kept sealed with antiseptic. An irrigation apparatus was demonstrated which provided an antiseptic seal and allowed the bladder to be washed out. This had been most successful in the prevention of sepsis. Although the risk of infection could be very considerably reduced by improved catheterization, this alone had been insufficient to prevent urinary sepsis in a small minority of men patients. In women a modification of the same apparatus might reduce the frequency of infection, but was unlikely to abolish it altogether. In view of the desirability of some additional protection it was recommended that patients about to undergo the operation of excision of the rectum be given two doses of vaccine, prepared from the bacteria which caused post-operative urinary infections, the first dose to be given as soon as possible after diagnosis, and the second after an interval of seven to ten days.

THE ROLE OF RADIOLOGY

The inaugural meeting of the Medical Society of University College, Dublin, was held in the College on November 14th. Dr. M. R. J. HAYES, in acknowledging the honour of being chosen president for the coming year, said he appreciated this all the more since it was bestowed at the moment when the status of the branch of medicine with which he was so closely identified had been raised to its rightful place in the curriculum.

Tracing the development of the science of radiology, Dr. Hayes paid a tribute to the pioneer work in Dublin of the late Dr. Lano Joynt and Dr. W. S. Haughton. The radiologist, he said, must not be blamed for the introduction of the "ready reckoner" methods of diagnosis, and if the high standards of the pro-Roentgen era were to be maintained it was the duty of clinical teachers to set the example to the student by making full use of all the ordinary means before calling on ancillary methods. The student should also remember that when he went out to practise he must rely on his own resources, and he must be able to assign proper values to symptoms and signs, for the services of well equipped departments would not then be at his disposal. The value of x-rays in the diagnosis of thoracic disease was now universally recognized, but they should not be employed as a short cut to early diagnosis. Sometimes the radiological findings might be conclusive, but nowhere was the correlation of clinical and radiological evidence more essential than in the diagnosis of thoracic disease. Wide variations were found in the x-ray appearances of the normal chest, and with the boundaries between the normal and abnormal so elastic there was scope for fallacy. Errors could be minimized, however, by prudence and common sense, and by a more thorough appreciation of the possibilities and limitations in the field of diagnosis by the radiologist and physician alike. In the diagnosis of pulmonary tuberculosis radiography almost invariably revealed the extent of the disease to be much greater than was suspected, and where there was clinical evidence of disease in one lung deposits were often found bilaterally. The radiogram was a trustworthy record, and a reliable aid in estimating progress, but the final judgement as to the activity of a pulmonary lesion must depend on the clinical manifestations of the disease. The introduction of the opaque meal had been one of the greatest advances in radiological science. If the diagnostic centre of gravity seemed to be shifting from the wards and the laboratory to the x-ray department in the recognition of one of the commonest and the most fatal of all abdominal diseases, the radiologist, while encouraged by this recognition of his science, was all the more conscious of his responsibilities. There were some, however, who thought him incapable of making any but "an x-ray diagnosis." The scientific radiologist must try to see the clinical perspective in his work equally with the clinician, who should endeavour to visualize the radiological perspective when summing up all the evidence and making his final judgement.

Dr. Hayes then passed in review recent advances in the applications of x-rays to the diagnosis of diseases of the gall-bladder and urinary tract, and in gynaecology, ophthalmology, laryngology, and dentistry, and noted some of the latest advances in radiotherapy. The ramifications of radiology were now so widespread that the question of instruction was becoming more urgent. During the anatomical course the reading of radiographic illustrations of bones and joints would form the groundwork of the interpretation of films. Films illustrating the growth of bone, the epiphyseal centres, supernumerary bones, and stereoscopic studies of the cranium would be very valuable. Stereoscopic views of the thorax after injection of cadaver with opaque media would give a mental conception of the pulmonary circulation and of the bronchi such as could be obtained in no other way. The full significance of abnormalities which the student saw later in the wards could not be understood without a thorough appreciation of the normal, which must be learned from anatomy. Since certificates of proficiency in radiology had become essential for candidates for certain appointments at home, it was most important that henceforth adequate instruction should be given in this new subject.

Reviews.

EWING'S "NEOPLASTIC DISEASES"

No treatise on tumours has received such widespread recognition as Ewing's *Neoplastic Diseases*.¹ It has been well merited. Probably no other author has brought to the task of compiling a complete textbook on the subject of tumour growths the same combination of great pathological experience, intimate acquaintance with the clinical aspects, mature judgement, and extensive knowledge of the literature. Published first in 1919 it soon became the standard work on new growths. A second, not much changed, appeared in 1922, but this, the third edition, has been considerably revised, so that it contains practically everything of note that has been added to our knowledge in recent years. The main alterations are to be found in the chapter devoted to tumours of bone and bone marrow. Thanks to the information collected by the Codman Registry of Bone Sarcoma, and more especially to the large experience of Professor Ewing himself, this section gives a much needed clarity and order to what has hitherto been a chaotic group of tumours. Considerable changes will be found, too, in the section devoted to brain tumours, and the classification of mammary cancers has undergone simplification.

It would be strange to come across any pathological laboratory where this book did not show the signs of frequent consultation. To the surgeon it is a necessity if he would seek to be more than a mere operator. The specialist and the practitioner will find it a mine of useful information.

The volume is divided into two main parts, the first dealing with the general aspect of neoplasms, history, classification, chemistry, theories of causation, and experimental research, and the second devoted to a detailed consideration of tumours according to the organs or tissues affected. Every chapter is practically a monograph on the particular department with which it deals, and all are excellent. One of the features of the book is the illustrations, of which there are as many as 546, and they are models of what textbook illustrations should be. Almost all are admirably clear and informative photographs of specimens and histological sections, chosen by one who has not only an eye for a photographable piece of a section, but a wealth of material at his disposal.

At the end there are over fifty pages of bibliography, from which the student may gain access to the original communications on any particular tumour. A rough calculation shows that there are about 6,000 such references—a demonstration of the immense amount of reading on the part of Professor Ewing. These references, the author tells us, "have all been verified by two competent bibliographers, and are believed to be accurate."

TREATMENT OF GASTRIC AND DUODENAL ULCER

We have received the fourth edition in Spanish of the monograph by Professor F. FERNÁNDEZ MARTÍNEZ on the treatment of the gastro-duodenal ulcer,² and also a translation of this work into French³ for the Practical Medicine and Surgery Series, which has been appearing at intervals during the past few years. The book contains a very clear account of the modern position with regard to this important subject, and the author's personal view is made clear in his dictum that ulceration of the stomach and duodenum is a malady which can be cured by medical treatment properly applied and properly directed. Attention to detail is of the utmost importance, and the bulk of the book is concerned with this in four sections dealing in turn with rest, dietetic treatment, medical treatment, and the author's own method. He quotes freely from

¹ *Neoplastic Diseases*. By James Ewing, A.M., M.D., Sc.D. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1923. (Roy. 8vo pp. 1127, 646 figures, 63s. net.)

² *Tratamiento de la Úlcera Gastro-duodenal*. Fidel Fernández Martínez. Segunda edición. Madrid: Javier Morata, 1928. (5½ x 8, pp. 277, 13 figures, 6 plates.)

³ *Traitement de l'Ulcerus Gastro-duodénal*. Paris: Masson et Cie. (12 fr sans majoration.)

authorities, with comments as to the advisability of the various forms of treatment advocated, and in a very important section considers the treatment of the complications of gastro-duodenal ulceration. The eradication of sources of infection he regards as of great importance, and there is a particularly wise section on the treatment of pain in this condition. The concluding part of the work is concerned with surgical measures, and here the author is at pains to be judicious in his summing-up of the position. The book is thoroughly up to date—as, for example, in mentioning x rays in the treatment of gastric ulcers.

LACTIC ACID IN BLOOD AND URINE

SUPPLEMENT XXIV to *Acta Medica Scandinavica* comprises yet one more of those elaborate reports upon biochemical investigations of the blood which that journal appears to have made it its special duty to publish. The subject in this case is the *Investigation of the Concentration of Lactic Acid in Blood and Urine*,⁴ and the author is Dr JERVELL. It is not possible to give in brief space an account of the great variety of conditions under which determinations have been made. Suffice to say that all those who may be interested in the relation of the concentration of lactic acid to diet, muscular activity, oxygen supply, and phosphorus metabolism will here find much material for their consideration. In respect of the pathological field it is recorded that the lactic acid of the blood is often increased in cases of cardiac insufficiency, and that the normal rise with muscular activity is found to be greatly accentuated. In anaemia, on the other hand, increased lactic acid is only found in the blood if the organism is unable to compensate for the reduced oxygen capacity of the blood by an increase in minute volume. In pneumonia, in pulmonary tuberculosis, and in spastic conditions, hyperlactacidaemia is frequent. It is not a primary symptom in fever, nephritis, liver disorders, or carcinoma.

We think it unfortunate that the author has chosen to employ a method of estimation not generally practised. There are available well-tried methods which yield consistently lower results than does that here employed. In this matter of the concentration of lactic acid in biological fluids it will be agreed that the lower results are generally nearer the truth. At the same time, the author's arguments are comparative only, and we do not suggest that our technical criticism questions these.

POPULAR BOOKS ON HEALTH

THE mass production of books on health for lay readers is being speeded up each year. The public, it appears, is hungry for this knowledge, so hungry that in the opinion of some publishers it will swallow anything it is offered. The great idea apparently is to go on feeding it, it does not matter in the least with what. So, we have heard, in famine areas people will eat earth and stones, not under the delusion that these may contain nourishment, but to enjoy the sensation of a loaded stomach.

Of the popular health books of to-day it may be said that a little of the pabulum offered to the public is very good, the bulk of it is poor, and some is definitely bad. In the first category is *What you should know about Health and Disease*,⁵ by Dr HOWARD W. HAGGARD, a book designed to instruct the lay public in the scientific foundations on which the structure of hygiene must be erected, and to display in a broad survey the whole field of modern medicine. These are ambitious aims, yet the author achieves them. The chapters on physiology are admirable—well arranged, clearly and simply written, and amply stocked with accurate, up-to-date information. The account of the practice of medicine is to be commended not only to the lay reader but to the first-year medical student who would like to have one good look at the forest before he concerns himself exclusively with trees. The value of this section

of the book to the general reader is that it shows him medicine not as an esoteric mystery to be revealed only to the specially endowed, but as a logical superstructure on established scientific fact. In these days, when the practice of medicine is making increasing demands on the patient's power of co-operation, when impressive guesswork is giving place to the patient accumulation and synthesis of data from biochemical and other sources, a public has to be created with a new attitude towards medicine.

Practically all that has been written of Dr Haggard's book would apply with equal force to another American work, *Personal Hygiene Applied*,⁶ by Dr JESSE FEIRING WILLIAMS, first reviewed in our issue of February 10th, 1923, and now in its third edition. The two books, indeed, bear a close resemblance, both in aim and method, but the latter ranges a little wider. The author is not content to give an account of the foundations and methods of modern medicine, he carries the war into the enemy's camp, and the field is strewn with the battered remains of osteopaths, chiropractors, Christian Scientists, patent medicine vendors, and the vultures who prey on the victims of chronic disease. It is a book that any doctor may safely recommend to his more intelligent patients.

Keeping Young after Forty,⁷ by Dr EUGENE R. WHITMORE, is a little more restricted in its aim than the two books just considered. The author attempts, however, to correlate hygienic advice with an account of the bare minimum of physiology and pathology on which it is based, and he writes with a sanity and freedom from sensationalism that is all too rare in books designed to fortify the courage of the middle-aged. Mr Bernard Shaw, in one of his plays, has suggested that men must try to live very much longer if for no other reason than that the problems of adaptation in our complex modern society are so great that most of us remain adolescents, still unlearned in the adequate reactions to the difficulties besetting us, almost until it is time for us to die. Mr Shaw, as a neo-Lamarckian, believes that some people may live to 300 because they "will" to do so, just as he believes that the giraffe grew a long neck for the same reason. Evolution, however, is more fertile in its expedients. The giraffe need never have troubled to grow a long neck if he had grown a better brain, then he might have invented a ladder. A man will make his adaptations to a changing environment not so much by altering his structure as by inventing ladders. He will have a longer and healthier life by probing deeper and deeper into the problems of physiology and pathology, and by applying the results of his discoveries to his body and to its environment. It is to be regretted that most of the books purporting to instruct the general reader in the technique of keeping young are written by the victims of obsessive neuroses. Dr Whitmore's book may be recommended because the author, although he confines himself to the subject of how to keep young, has succeeded in not discovering the elixir of life.

NOTES ON BOOKS

THE poor father has been too much neglected by the flood of literature provided for the education of parents. At the maternity and child welfare centre his very existence seems to be forgotten, or remembered only to be abused. At last someone has thought of educating him, and we are glad to find that one of the authors of the father's guide is a medical man himself face to face with parental problems. In *On Being a Father*⁸ the instruction is given with a plentiful spice of humour—the same sort of whimsical entertainment Mr KENNETH WALKER gave us in his earlier book *The Log of the Ark*. The illustrations are excellent, and a great ornament to the book. Every middle class father should read this little volume, but he ought to get it before the baby is born because the chapters on the expectant father are among the best.

⁴ *Investigation of the Concentration of Lactic Acid in Blood and Urine under Physiologic and Pathologic Conditions*. By Otto Jervell. *Acta Medica Scandinavica Supplementum xxiv*. Oslo: Nationaltrykkeriet, 1928. (Med. 8vo pp. 135.)

⁵ *What you should know about Health and Disease*. By Howard W. Haggard. With an Introduction by Landell Henderson. New York and London: Harper Bros. 1928. (Demy 8vo pp. xiii + 5.8, 74 figures, 15s. net.)

⁶ *Personal Hygiene Applied*. By Jesse Feiring Williams, A.B. M.D. Philadelphia and London: W. B. Saunders Company, 1928. (Post 8vo pp. 438, 29 figures, 10s. net.)

⁷ *Keeping Young after Forty*. By Eugene R. Whitmore, B.S. M.D. New York and London: D. Appleton and Co. 1928. (Cr 8vo pp. viii + 278, 6s. net.)

⁸ *On Being a Father*. By E. M. and R. M. Walker. With an Introduction by Cecil Delella Burns. London: J. Cape, 1928. (Cr 8vo pp. 191, illustrated, 5s. net.)

Mr HOUSTON PETERSON'S work on *Havelock Ellis*⁹ contains a sympathetic study of a man who is equally well known as the principal founder of the scientific study of sex and as a distinguished man of letters. As likely to be of special interest to our readers we may recommend the chapters entitled

Physician and surgeon, 'The sex theme', 'Havelock Ellis on trial', and 'Fieud and Ellis'. Bibliographies of Dr Havelock Ellis' principal books and other contributions to literature, as well as of the numerous translations of his works into foreign languages, are appended.

Since the first edition of Dr GERSTMANN'S book on the malaria therapy of general paralysis¹⁰ (see *Journal* September 12th, 1925 p 481) the number of cases treated in the clinic of Professor Wagner Jauregg who first introduced the method, has risen to over 2,000, and an enormous literature on the subject has accumulated. The second edition of which we have received a copy, has been enlarged by 80 pages and of these nearly 30 are devoted to the bibliography as compared with barely 15 pages in the first edition. The text has been revised throughout. Some of the sections have been rearranged, and two new sections have been added dealing respectively with the condition of the parasites in preserved malarial blood and the treatment of general paralysis with other infections, besides malarin and relapsing fever, such as rat bite fever, framboesia, living strains of *Spirochaeta pallida*, and a proprietary preparation consisting of a mixture of non-pathogenic micro-organisms. Almost all authorities, however, are agreed that these substitutes are inferior to tertian malaria in the treatment of general paralysis. The experience of the last three years has confirmed the author in his belief that general paralysis is no longer an incurable disease and the degree to which it can be affected depends merely on the stage at which the treatment is applied, the most important principle being to start it at a sufficiently early date.

The little work on microbial associations and their therapeutic applications,¹¹ by Drs G. PAPACOSTAS and J. GATÉ of the Institut Pasteur of Lyons, is the latest addition to the *Bibliothèque de Microbiologie*, edited by Professor F. Bezançon which in turn forms part of the *Encyclopédie Scientifique*, of which Dr Toulouse is the general editor. The book is divided into three unequal parts. The first and shortest consists of two chapters devoted respectively to the consideration of symbiosis and parasitism in vegetables, animals and bacteria. In the second part the writers discuss the association of various micro-organisms *in vivo* and *in vitro*, showing that the action of one micro-organism upon another may be of four different kinds—namely, one of stimulation like that of *Cladotrix* on the diptheria bacillus, antitoxin or secretion by certain species of micro-organisms of products injurious to other species living in the same environment, like *B. pyocyaneus* which has a destructive effect on a large number of other organisms, synergy, which is usually one-sided, like that of *B. proteus* on the pneumococcus, but occasionally reciprocal, as in the case of the streptococcus and typhoid bacillus and lastly, antagonism, like that between *B. pyocyaneus* and *B. anthracis*. The third part is devoted to the practical application of microbial antagonism or bacteriotherapy, of which the most important examples are the treatment of various conditions by lactic ferments, *B. pyocyaneus* and pyocyanase, and yeasts. An extensive bibliography, which is much more international than that usually found in French works, is appended.

*Practical Biochemistry for Students*¹² by Professor E. W. H. CRUICKSHANK is a textbook written to meet the needs of the medical students of Patna University. In that university biochemistry follows organic chemistry, but wholly precedes physiology. The author, therefore, has to present his subject in a very elementary manner, without assuming any knowledge of physiology. He has succeeded in compiling a very simple but clear introduction to the study of biochemistry which is well worth the attention of those teachers who are confronted with a like problem.

⁹ *Havelock Ellis: Philosopher of Life*. By Houston Peterson. London: G. Allen and Unwin Ltd. 1928. (Med. 8vo pp. xiii + 432. illustrated. 18s. net.)

¹⁰ *Die Malariabehandlung der progressiven Paralyse*. Von Privatdozent Dr. Josef Gerstmann. Mit einem Vorwort von Prof. Dr. Julius Wagner Jauregg. Zweite, neubearbeitete und wesentlich vermehrte Auflage. Wien: J. Springer. 1928. (Roy. 8vo pp. vi + 305. 17 figures. R. M. 22.40. bound. R. M. 24.40.)

¹¹ *Les associations microbiennes. Leurs applications thérapeutiques*. Par Georges Papacostas et Jean Gaté. Paris: Doin et Cie. 1928. (4½ x 7 pp. 438. 20 fr.)

¹² *Practical Biochemistry for Students*. By E. W. H. Cruickshank, M.D. Aberd., D.Sc. Lond., Ph.D. Camb., M.R.C.P. Lond. Calcutta, and London. Butterworth and Co. Ltd. 1928. (Roy. 8vo pp. viii + 275. 21 figures. 12s. 6d. net.)

The chemical contribution to the study of induced anaesthesia¹³ is the title of a thesis by Dr G. LORENCE. The author studied a series of isomers of the ureid of bromo valerianic acid. He measured the oil-water distribution coefficient and the narcotic dose of each derivative, and endeavoured to correlate the chemical constitution, physical properties, and narcotic action. The work was done under the inspiration of Professor Fournieu.

Dr W. F. LLOYD has published a booklet of naive little plays, of which the setting and sentiment will appeal, we imagine, to Welsh rather than to English audiences. In *The Welsh Fasting Girl*,¹⁴ which gives its name to the volume, is set forth a true story of a justic maiden who maintained a bogus fast for the pecuniary benefit of her family. The heroine dies on the stage in a mingled odour of sanctity and fraud, a Welsh doctor and a Welsh nurse from Gwynedd discover the simple trickery, but are prevented by a lofty sense of moral and professional rectitude from interfering with the natural consequences of patiently imposed starvation. A farce entitled *The Locum* depicts the trials and troubles of a doctor whose best patient is first cured, and then supposed to be done to death, by a newly qualified youth, who seems to be ignorant alike of the use and abuse of drugs. Another little play, *Cwm Farn*, abounds in passages from the Scriptures by an aged grandmother, whose voice during quotation gradually rises to a 'hwy!' Doubtless Dr Lloyd is correct in suggesting that the plays will be more effective, if given before a bilingual audience, with the judicious introduction of some Welsh expressions.

PREPARATIONS AND APPLIANCES

FORCEPS FOR SIMPLIFYING RAMMSTEDT'S OPERATION

Mr G. D. F. McFADDEN, M.Ch., F.R.C.S. (Belfast) writes: In performing Rammstedt's operation for hypertrophic pyloric stenosis, undue delay and increase in shock are frequently caused by the intestine and omentum protruding from the wound. This protrusion is due to the size of the incision necessary for the fingers to grasp the pylorus, and to the light anaesthesia produced by the gas and oxygen mixture which is the anaesthetic of choice. To eliminate these difficulties and simplify the operation I have devised a special pair of forceps which are very useful. These forceps have their grasping ends shaped like a pair of midwifery forceps, and are lightly constructed to prevent any harm being done to the tissues. The handles are fitted with a ratchet, the first teeth of which lock before the grasping ends are in contact, the other teeth taking purchase as the forceps are closed. In this way the varying size of the hypertrophied pylorus in infants is allowed for. The forceps are made with a curve to permit the handles to lie flat on the abdomen when the pylorus is pulled up into the wound. With this instrument the peritoneum need only be

incised sufficiently to admit one finger. The finger is passed down to the pylorus. The forceps, held in the other hand, is then passed along the finger to the pylorus, which is grasped and pulled out through the wound, no other of the abdominal contents has an opportunity to protrude. When the pyloroplasty is completed the pylorus is allowed to drop back and the incision in the abdominal wall is closed. These forceps have been constructed for me by Messrs Allen and Hanburys, Wigmore Street, London, W.1.

QUININE FOR INTRAMUSCULAR INJECTION

Solvochin and transpulmin (E. H. Spicer and Co., Ltd., Watford) are preparations of quinine in a form suitable for intramuscular injection. Solvochin is a 25 per cent aqueous quinine solution with a neutral reaction and it is said to be non-irritant on intramuscular injection. Transpulmin is stated to be a solution of basic quinine and camphor in 'ether-oil', by this term we presume that volatile oils are meant. The vendors recommend these preparations of quinine particularly for use in pneumonia, and they put forward some very remarkable claims concerning the pharmacological actions and the clinical effects produced by these drugs.

BRITISH INSTITUTE OF RADIOLOGY

MEETING IN LONDON

THE British Institute of Radiology, with which the Röntgen Society is now incorporated, held what was virtually an annual congress from November 14th to 16th at the Westminster Central Hall. The lectures and discussions were combined with an exhibition of x-ray apparatus and photographic materials, to which the leading firms contributed. The president of the Congress was Dr G. W. C. KAYE, director of the Physics Department of the National Physical Laboratory, and the principal events were his presidential address, the Mackenzie Davidson Memorial Lecture, by Professor W. L. Bragg (the subject of an annotation elsewhere), the Silvanus Thompson Memorial Lecture, by Mr Sampson Handley, various papers on physical subjects, and a medical discussion, under the chairmanship of Sir Humphry Rolleston, on the value of the opaque meal in diagnosis. The principal contributors to this discussion were Sir Thomas Horder, Mr A. J. Walton, and Dr A. E. Barclay, who dealt with it respectively from the position of a physician, a surgeon, and a radiologist. Each of them discussed the special considerations relating to the stomach, duodenum, and large and small intestine, but they also made some observations of a general kind on the value of radiology.

Sir THOMAS HORDER said that he still believed that if patients were parcelled out amongst radiologists, bacteriologists, and biochemists, the practitioner of clinical medicine was not doing his best for them. Instrumental and graphic methods had become so prominent of recent years in the diagnosis of disease that clinical medicine was almost a Cinderella. Patients were rather surprised when the consultant did not at once unpack their collection of radiograms. But even the best—perhaps in one sense especially the best—set of radiograms might contain a whole heap of appearances which were irrelevant so far as the patient's disease was concerned, on the other hand, they might contain appearances which were like a revelation to the observer whose eye had been sensitized to this particular case by thorough acquaintance with the patient. The great art of diagnosis did not lie in the accumulation of a vast quantity of data, nor in trying to establish superiority for one set of data over another, but in separating the essential from the non-essential. It was a truism to say that the contribution made by radiology to the diagnosis of diseases of the alimentary tract was incalculable, but the contribution would be still greater if consulting rooms were not still flooded with a large amount of indifferent work. Nothing darkened counsel so much as a bad radiograph. Sometimes, after having been faced with such a series, he felt that if one could only neglect the whole lot and rely upon other methods the case would be less difficult, but then there came such a splendid series of pictures, of exquisite technique, that he was lured back to a pardonable reliance upon the method. He concluded with a warning addressed to clinicians as well as radiologists, that it must not be thought that as technique improved and results got better the interpretation of them became more easy, the contrary was the case.

Mr A. J. WALTON said that not only the public but able practitioners were beginning to regard x-ray investigation, carried out even by an untrained man, as a valuable means of diagnosis. A large number of patients had wasted both time and money on useless investigations, which had to be repeated at a later date, because too much reliance was placed upon the x-rays. Cases were sent up for an x-ray picture to determine whether a certain lesion was present when the most superficial clinical examination would have made the matter clear. Again, cases of doubtful stomach or intestinal lesions were sent up with one poor film taken by an amateur, and accompanied by no report. This was not only wasteful but dangerous, because it subjected the patient to unnecessary x-ray exposures, gave rise to erroneous diagnosis, and brought into being a false sense of security. On the other hand, careful investigation by a man well trained in this branch of work and accompanied by a detailed report was of inestimable value.

Dr A. J. BARCLAY admitted at once that no elaboration of apparatus or perfection of technique would of itself give accuracy of results. This was not, and never could be, a machine-made diagnosis. There had been two discussions recently on pitfalls and fallacies in radiological diagnosis—one at the Royal Society of Medicine and the other at the Annual Meeting of the British Medical Association. Commenting on these, the writer of a very able leading article in the *British Medical Journal* on October 6th (p. 617) laid his finger on the weak point, the biggest fallacy of all, the fact that those in authority had not realized the vital importance of obtaining the services of the best men available for this very specialized task. But the radiologist also could point out clinical mistakes. Very often radiological and clinical conclusions were at variance, but by the operation findings the radiological report was shown to have an extraordinary degree of accuracy—an almost unbelievable accuracy to those of them who had seen the whole method evolve from its infant fumbings. The diagnosis of conditions in the abdomen was inevitably difficult, without radiological examination it was nothing more than intelligent guesswork, but with a competent and thorough radiological examination this guesswork was correlated with the facts of actual observation, and the deduction of an accurate diagnosis became a possibility. The radiologist deduced from shadows that recorded facts, the clinician had to rely on signs and symptoms which, in the abdomen, were as uncertain as an English summer.

Dr H. E. GARDEN and Dr GILBERT SCOTT spoke briefly, and at a later session the subject was resumed, and several speakers gave their experiences.

Annual Dinner

The annual dinner of the Institute was held at the Trocadero on November 16th, when Dr G. W. C. Kaye presided over a large company, including many eminent guests. Before any of the complimentary toasts were taken, these present stood in silent memory of Robert Knox. Mr CUTHBERT ANDREWS, in a witty speech, proposed the health of the Institute. The amalgamation, he said, had not yet been perfected. It was a new venture, with more difficulties than the outsider could appreciate, but he had every hope for its future success. "It is going to be the best and most complete thing of its kind in the world." Dr KAYE, in response, said that this November meeting, the second of its kind, had done fair to become an annual congress. The attendance had been wonderfully good, the discussions well sustained, and that dinner was a happy reunion of friends in town and country. The Institute included in its membership and activities three elements—those represented by medical men, by physicists, and by manufacturers. The trinity had been described as faith, hope, and charity, but he would not venture to say which was which! In response to the toast of "The Guests," proposed by Dr L. A. ROWDEN of Leeds, Sir THOMAS HORDER referred to a number of radiological pioneers whom he had known and all of whom in their different spheres he honoured—Robert Knox, Archibald Reid, Hugh Walsham, Lewis Jones, and Ironside Bruce. He believed that there was no ancillary science which gave clinicians so much help as radiology, not even excepting the science of bacteriology, and he maintained this in spite of a paragraph which appeared in one of the London journals that evening, under the heading of "Bad radiology," purporting to give some of his remarks in the discussion of the morning. Mr H. T. TIZARD, F.R.S., secretary of the Department of Scientific and Industrial Research, who also responded, praised the close co-operation of medical men and men in adjoining fields of science which the Institute exemplified and furthered. Colonel KENELM EDGECOMBE, president of the Institution of Electrical Engineers, congratulated the Institute upon its splendid achievement at the recent International Congress of Radiology at Stockholm in getting the British point of view of the subject of protection adopted by a gathering representative of many countries. Sir HUMPHRY ROLLESTON called upon the company to drink the health of the chairman and said how much the work of the X-ray and Radium Protection Committee had been facilitated by Dr Kaye's efforts.

HOSPITALS PAST AND PRESENT.

PRESIDENTIAL ADDRESS TO THE LONDON ASSOCIATION OF
THE MEDICAL WOMEN'S FEDERATION

At a meeting of the London Association of the Medical Women's Federation, held on October 23rd, at the House of the British Medical Association, Dr FRANCES HUXLEY, the new president, delivered an inaugural address on the scope and trend of hospitals past and present.

Dr Huxley traced the origin of institutions for sick poor from ancient Babylon where the sick were placed in the public ways so that passers by might give advice as to treatment. In the earliest refuges for the sick the care of the soul and the body were closely associated, and rested in the hands of the priests. In ancient Greece the rite of incubation was practised in temples raised to Aesculapius. By this rite, also practised in Egypt, sufferers from disease slept in the shade of the temple, that the god might inform them in their dreams of their treatment. A papyrus, named after Professor Ebers, and dating from circa 1550 B.C., gave detailed information about a hospital associated with the temple of Heliopolis. Excavations of ancient Egyptian shrines resulted in the uncovering of the great temple of Dindara, with Laboratory Officers over one door, and Place for the Preparations of the Superintendent of the Laboratory over another. The date of this also was about 1500 B.C. In Egypt, in the eleventh century B.C., there was a college of physicians in receipt of public pay, and regulated by law as to the nature and extent of their practice. Women were said to have practised there. The physicians had to treat the poor without fee and there were probably, as later at Athens official houses where the poor attended corresponding with out-patient departments of to-day. The physicians were allowed to receive payment from private patients. There were already then specialists, and each was allowed to practise only his own branch of medicine.

In Greece, by the fourth or fifth century B.C., there were as many as 300 temples where the healing art was practised. One was at Epidaurus. From the time of Hippocrates who was born in Cos about 460 B.C., a splendid hydropathic hospital developed there in association with the old temple. Hippocrates used to prescribe sunlight, pure air, pure water, and shelter from cold winds—a good basis for modern treatment. At about the same time numerous hospitals sprang up in the East, at first associated with Buddhist monasteries. In China only was there no record of them. In the Buddhist period Charaka and Susruta practised laparotomy, the suture of intestines, and rhinoplasty. The ruins of one Buddhist hospital remained at Surat, and others were still extant in Burma and Siam. In the early days in Persia, Greek physicians had seized the court. A hospital with a medical school existed at Gondishapur, in Persia, and about A.D. 550 Barjora was sent to India to study the Buddhist medical system. After this the school and hospital, under the combined teaching of the West and East, was a great centre of learning for many generations. While Europe was in complete cultural ignorance this school giving rise to medical education in the Moslem world, produced several hospitals. In 1295 the Grand Vizier Rasidu built a hospital at Tabriz and sent agents to foreign countries to collect good and rare drugs. There was a staff of oculist surgeons and physicians and students employed as clerks and dressers.

Only with the acquirement of scientific knowledge from Greece was the native Roman delivered from pagan practice. Asclepiades taught in Rome. A follower of his Celsus described plastic operations on the face, the removal of nasal polypus, and operations for goitre and stone. The Romans excelled in the development of hospitals. Valetudinaria were built primarily for infirm soldiers, but later for the use of citizens, rich and poor. A Roman matron Fabiola built a type of hospital known as nosocomium, and linked up convalescent homes in the country with institutions in Rome. In A.D. 335 Constantine abolished many Roman hospitals but the edict probably concerned only pagan shrines. Before the Christian era women were already practising medicine perhaps in Egypt, certainly in Greece and Rome. Hyginus recorded that before the practice of medicine was permitted to women in Greece one Agnothe studied medicine unrecognized. Her practice was successful, jealousy was aroused and she was brought into court for breaking the law. However, her women patients protested and the laws were modified so that any free woman might practise in Greece.

While Christians were still oppressed the care of the sick had to be undertaken secretly by deacons. As Christianity

became established the bishops were made responsible for such care, and hospitals were built in the vicinity of the bishops' dwelling. Later hospitals associated with monasteries spread throughout Europe. In England in the Middle Ages numerous hospitals were founded, but, being ecclesiastical foundations, they were for the cure of the soul rather than of the body. Most of them were not hospitals in the modern sense of the word, it was difficult to get any record of institutions for the care of the acutely sick. Among the earliest English hospitals were St Leonard's at York and a house at Flinton, also in Yorkshire, both founded in the tenth century. In 1123 Rahere founded the Hospital and the Priory of St Bartholomew. The hospital was run by a master, usually a priest, eight brethren, and four sisters. After the dissolution of the monasteries in Henry VIII's reign, opportunities for in-patient treatment were scanty. By the beginning of the eighteenth century there were only two general hospitals in London—St Bartholomew's and St Thomas's—and one special hospital—namely, Bethlehem. In the country there were no hospitals, as late as 1736 cases requiring surgical treatment were forced to travel to London for it. To replace the provisions for the poor made by the religious charities until 1537 Queen Elizabeth had established a Poor Law system. Each parish was to provide work for its able-bodied and dwellings for its aged and infirm. The system was not satisfactorily carried out, because the parishes were not rich enough to build the required houses. In the latter half of the seventeenth century more workhouses were built, but Poor Law relief was very inadequate. Furthermore, the chartered hospitals, owing to lack of funds had limited very seriously their numbers of out-patients, and were charging in-patient fees. At Bart's in 1673 out-patients were limited to eight a week. This number was increased to fifty in 1695. A patient requiring admission, however urgently, had to have a governor's letter, or pay 19s. 6d. for burial fees. Fees were required also for the sisters and porters. The medical staff was salaried.

In the eighteenth century considerable impetus was given to medical study by the establishment of certain university chairs. There was also a great revival of religious feeling, which turned public attention to the state of the sick poor. The motive for securing the protection of the healthy gave way to a desire to alleviate the sufferings of the sick. In the eighteenth century the Westminster Hospital, St George's Hospital, the London Hospital, and the Middlesex Hospital were founded. The conditions of these voluntary subscription hospitals, as contrasted with the chartered institutions, were (1) they were unendowed and wholly dependent on the benefactions of the public, (2) their administration was in the hands of subscribers, (3) their medical and surgical staffs were honorary, and voted (as subscribers) on matters relating to general management, (4) no fees were taken from applicants for admission.

The Royal Free Hospital was founded in 1829 by Dr William Marsden. One evening, when passing St Andrew's, Holborn, he saw on the church steps a young girl almost dead from disease and starvation. She had been refused admission at Bart's because she had no governor's letter and no money. Dr Marsden opened a small dispensary to which the sick poor were admitted without payment and without formality, this was the beginning of the Royal Free Hospital. The general use of hospitals remained for some time limited. Hospital construction was faulty, sanitation primitive, and overcrowding the rule. Sepsis was rampant. It was only with the rapid progress of medical teaching, the acquirement of knowledge of asepsis and the development of a scientific nursing service, that hospitals began to assume their rightful position in the health scheme of the country.

In dealing with hospitals at the present day, Dr Huxley pointed out that after the war increased expense and decreased subscriptions had made the position of hospitals very serious. Temporary help was given by the Government, a grant of £600,000 having been distributed. Now the position was better, but voluntary hospitals, as charitable institutions for the free treatment of the sick poor, no longer existed. The voluntary hospital still received a proportion of its income from charitable sources, but it also received a large and growing proportion from patients' payments. Pay beds had come into being, and were being extended, the proportion of entirely free cases was small. Poor Law hospitals were being brought up to date and before long would be taken over by the local authorities. More co-operation between voluntary hospitals and municipal hospitals was bound to come in the future. Nearly everyone in England said Dr Huxley, regarded the voluntary system with great affection, and were anxious to maintain it, but all the voluntary system now meant was freedom from interference and red tape, and this could, in her opinion, be maintained only by making the voluntary hospitals self-supporting, and by a willingness on their part to co-operate with each other and with the municipal hospital service, which was rapidly coming abreast of them.

YELLOW FEVER PROPHYLAXIS

INTEREST in yellow fever and its prophylaxis has been awakened by recent reports and correspondence in the *Times* referring to a protective vaccine and its use in South America. The history of yellow fever investigations is both interesting and tragic, for others besides Adrian Stokes, Noguchi, and Young have lost their lives while probing into its secrets. The first definite advance in our knowledge of the etiology was made in 1901 by the American Commission, consisting of Reed, Carroll, and Agramonte, who, working at Quemados, proved that the vector was the mosquito *Stegomyia fasciata*, or, as it is now known, *Aedes argenteus*. It is true that many years before then both Beauprethuy and Finlay had suspected this mosquito, but the results of the American Commission placed the matter on a sure foundation. Two years later, at Rio de Janeiro, the observations were confirmed by the French Commission, composed of Marchoux, Saluberni, and Simond. This newly acquired knowledge placed at the disposal of hygienists a method of prevention of which they availed themselves to the full in Central and South America, largely under the auspices of the Rockefeller Foundation. The yellow fever mosquito, which breeds in collections of water in and around houses, was relatively easy to attack. By stringent regulations and untiring inspection it was found possible to keep the mosquito index below the critical level, so that yellow fever as a terrible menace has ceased to exist in the great foci in the New World. There is, however, always the danger that it will appear where the anti mosquito measures have not been applied, or should the energy of attack be abated. The disease is also endemic in West Africa, and from time to time occurs in serious epidemic form. Though some believed that the African disease was not yellow fever, there is no longer any doubt as to its nature.

It would appear that the application of the anti mosquito measures which have proved so successful in America presents greater difficulties in West Africa, owing probably to the more primitive native population. Thus being so, it was all the more desirable that some other method of combating the disease should be discovered. Great hopes in this direction were raised by the announcement by Noguchi in 1919 that he had isolated the causative organism—*Leptospira icteroides*—which was allied to that which produces infectious jaundice or Weil's disease. With it a vaccine was prepared and an antiserum in horses, and these were issued for prevention and treatment. Though some observers appeared to confirm Noguchi's findings, there gradually accumulated evidence that Noguchi's leptospira was identical with that of Weil's disease. At this juncture, in 1925, the West African Yellow Fever Commission of the Rockefeller Foundation went to West Africa, where medical officers in the Colonial Service had repeatedly failed to recover a

leptospira from cases of yellow fever. The late Adrian Stokes, who joined the Commission as a British representative, together with Bauer and Hudson, made the most important discovery that the disease was inoculable to Asiatic monkeys, particularly *Macacus rhesus*. In it the virus was easily maintained by direct inoculation of blood and tissues, or by mosquito transmission. Thus at once opened up a field for experimental investigation. It was shown that the disease was caused by a filterable virus and not by a leptospira. Noguchi then, as an independent worker, went to West Africa from the Rockefeller Institute, and commenced his work at Acera at the laboratory of which W. A. Young, who had long experience of the disease in West Africa, was the director. As is well known, Noguchi and then Young fell victims to the infection. Though Noguchi's results have not yet been published, it is understood they are in agreement with those of the West African Yellow Fever Commission, which was working at Lagos.

Finally, A. W. Sellards of Harvard University went to Dakar and with Mathis again confirmed the susceptibility of the Asiatic monkey. Sellards, as recorded in this *Journal*,¹ on his return came to London and brought with him frozen virus, which proving infective, enabled work to be carried on in this country. With this strain of virus Edward Hindle, the Beit Fellow in Tropical Medicine, carried out investigations in London at the Wellcome Bureau of Scientific Research. Applying to the experimental disease in monkeys the methods which had proved successful for the production of vaccines in the hands of Laidlaw and Dunlop in the case of dog distemper, and of Todd in the case of fowl plague, Hindle found, as noted in this *Journal*,² that a phenol glycerin emulsion of the liver would confer on monkeys an absolute immunity against enormous doses of virulent virus. Meanwhile Aragao (1928), working at the Oswaldo Cruz Institute in Rio de Janeiro, demonstrated the susceptibility of the Asiatic monkey to the South American disease, and by a cross immunity test proved the identity of the American and West African viruses. Receiving Hindle's paper on the preparation of vaccine, Aragao repeated the observations with the American strain, and, after administering the vaccine to a number of laboratory workers with no untoward results issued it for use in a small epidemic. In all, between three and four hundred people were vaccinated without accident, and, though no unwarranted conclusions are drawn, it is noted that none of the vaccinated contracted the disease. These encouraging results are being followed by the production of the vaccine on a larger scale, so that it will be available for use by the Public Health Department of Brazil.

One other aspect of the question deserves mention—namely, the protective action of immune serum of convalescents. It was shown by the French Commission in 1903 in the case of human beings and by Stokes, Bauer, and Hudson in monkeys, that a comparatively small dose of serum from a recovered case of the disease would protect against infection. There is here a method of diagnosis in doubtful cases which may be of the greatest service. Furthermore, convalescent serum will confer an immediate

¹ Sellards and Hindle. *British Medical Journal* April 23rd 1928 p 713.
² Hindle. *British Medical Journal* June 9th 1928 p 876.

immunity, and will have its uses when it is desired to immunize more rapidly than by vaccine. Inducible vaccine, however, if it proves to be as effective in human beings as it is in monkeys will be of the utmost value in the prevention of yellow fever, which hitherto has depended on a precarious and ceaseless vigil over the ubiquitous insect vector.

NOISE AND THE PUBLIC HEALTH

THE British Medical Association has reason to feel gratified at the reception accorded by the press to its Memorandum on Preventable Noises, submitted to the Minister of Health on October 23rd and published in the *Supplement* to our issue of November 10th. Most of the great national newspapers have made the memorandum the subject of favourable, even enthusiastic, leading articles; nearly all of them have given it prominent notice on their chief news pages and quoted extensively from its proposals. Not merely public support, but public gratitude is due to the British Medical Association for the forcible memorandum which they have addressed to the Minister of Health on the subject of preventable noises. It emphasizes with the weight of those speaking with authority, the very serious injury to which the health of the community is exposed by the conditions of the present day—conditions which have been created by the mechanical age and allowed to accumulate until they have become intolerable. The British Medical Association's Memorandum to the Minister of Health about the noise nuisance represents the best medical opinion seriously applied to a practical question. We should ignore it at real peril to our health. 'It is the most forcible statement of the case concerning the damage to health from avoidable noise that one has seen. We quote these typical extracts from the daily press because we believe they represent a widespread feeling that the British Medical Association has done a service to the community by insisting that the problem of noise is closely bound up with the public health. This, so far as it goes, is all to the good. It means that the public now realizes that something more is threatened than its comfort, that its mental and physical health is endangered by the incessant din of to-day. But it must not be taken to mean that the Association may now gracefully accept the bouquets that have been showered on it and regard this piece of work as accomplished, or that the public, secure in the belief that something is now certain to be done, may once more sink into inertia. The price of freedom from noise is eternal vigilance.

There are already signs that Mrs Partington is getting busy with her mop. The traffic experts, it is said, are preparing to solve the whole problem by standardizing the motor car horns to be used in city streets. There is a real risk that their proposal may be accepted, and the public told that the noise nuisance has now been taken in hand. A premature closing of the campaign might very well leave us where we were—the noise from electric hooters perhaps abated a little, but all the other components of the general pandemonium left untouched, and, for all one knows, even intensified as the years go by. Thus while the Minister of Transport is showing how severe it can be with a whipping boy, the other offenders must not be allowed to continue their clatter and din. The Government should be made to understand that tinkering with this huge problem is a waste of time and that comprehensive measures on the lines suggested

by the British Medical Association are needed to abolish the curse of unnecessary noise. Here we would repeat that noise and speed are so closely interrelated that any attempt to deal with the one without controlling the other is doomed to failure. Unfortunately, a large section of the public wants more and more speed. These restless folk appear to believe that motion relative to the earth is the thing that really matters, and in this belief they devote the greater part of their lives to what is to them the all important business of getting somewhere else in the shortest possible time. Devotees of sheer speed will not willingly acquiesce in radical proposals to lessen the din of traffic.

Meanwhile we welcome the news that at a recent meeting of the Edinburgh Town Council it was unanimously resolved to take immediate steps, by a clause in the next Provisional Order, to secure legislation along the lines of the British Medical Association's resolutions on noise. This, so far as we know, is the first attempt to deal with the evil by local legislative action. It is fitting that Edinburgh should give a lead in this matter. The Edinburgh and Leith Division of the British Medical Association was the first responsible body to initiate a campaign against noise and vibration on the ground that these are a menace to the public health. In October, 1927, Dr T G Nasmyth and Judge Monson Millar, of the Public Health Committee of the Edinburgh Corporation, invited their committee to consider the question of preventable noise, especially noise at night, in its relation to the public health, and in May, 1928, the Public Health Committee approved and supported the resolutions formulated by the Edinburgh and Leith Division, and then about to be forwarded for inclusion in the agenda of the Annual Representative Meeting of the British Medical Association at Cardiff. We hope that other municipalities will follow the example set by the Scottish capital, and that the public agitation against noise will not be allowed to die down.

THE INTERNATIONAL CANCER CONGRESS

A FEATURE of the present age is the holding of conferences, and there is no doubt that in elucidating questions of etiology and treatment much assistance can be derived from the joint consultation of experts from various countries who approach the same problem from different standpoints. The ultimate value of such co-operation depends, however, upon the extent to which the information thus made available can be considered at leisure, and therefore the appearance this week of the full official report of the International Cancer Conference,¹ which, on the initiative of the British Empire Cancer Campaign, was held in London last July, is much to be welcomed. In our issues of July 21st and 28th we dealt at some length with the outstanding contributions of various distinguished workers to the discussions on that occasion, and the extent of the ground that was covered in the conference makes it impossible to discuss at all fully here any particular part of the present volume, or even to enumerate the titles of the many papers. It can be said with confidence, however, that this volume will long be a most valuable book of reference, in some respects it is a textbook with which all interested in cancer research will have to be familiar. Professor Archibald Leitch, the editor of the report, deserves high credit for the way in which the vast amount of scientific information has been made available for quick reference and careful study. The report is arranged in sections according to the subjects

¹ *International Conference on Cancer* London 1928 Bristol J Wright and Sons Ltd London Simpkin Marshall Ltd 1928

discussed. The first section is devoted to consideration of the causes of cancerous growth and the mechanism of the cell changes, and the opening paper by Professor James Paving of New York sums up in a readable manner the chief recent developments in this respect. Here and elsewhere in the papers comprising this section are signs of the variety of directions in which research is proceeding to trace the principal factors implicated. The second section is devoted to the relative values of surgery and radiation in the treatment of cancer, and contains what are possibly some of the most interesting and provocative contributions to the whole conference, outstanding prominence is necessarily accorded to radium, which, by general consent, has

come to stay." A shorter, though important, section is devoted to methods of treatment by chemotherapy, with special reference to lead. A considerable amount of opposition to this line of treatment was manifested at the conference, and it is clear that a settled judgement has not yet been reached. From the pathological standpoint the discussion on occupational cancer was of considerable significance, and illustrated plainly how circumstances vary in different countries. Mention may here be made of an authoritative paper, contributed by medical inspectors of factories under the Home Office, relating to the occurrence of cancer in industries. On the surgical side special attention is paid to the early recognition and treatment of gastric cancer and of bone sarcoma, while medical interests were uppermost in the consideration of cancer cachexia and pulmonary carcinoma. Many diagnostic methods are discussed, and several papers relate to the effects of radium and x rays on the blood, vascular, and lymphatic systems, with special reference to malignant growths. The report concludes with statistical papers on the geographical and racial prevalence of cancer, and practical conclusions are deduced with regard to public action, including cancer campaigns and the provision of anti-cancer centres.

THE MOLECULE UNDER THE X RAY MICROSCOPE.

THE late Sir James Mackenzie Davidson once expressed regret that he had not devoted his career wholly to physics instead of to medicine. One can imagine with what delight he would have listened to the eighth Mackenzie Davidson Memorial Lecture which was delivered at the House of the Royal Society of Medicine on November 14th by Professor W. L. Bragg, F.R.S., on the new science of x-ray optics. The lecturer, who furnishes a happy example of how a genius for science and its exposition can be transmitted from father to son, made this recondite subject as clear as it can be made to any audience simply by pursuing the analogy of x rays and light rays, and showing how the examination of atomic arrangements by the former is only an extension of the examination of small bodies under the microscope. At the outset Professor Bragg complained of the term "x ray," which, he said, should be "x wave." The word "ray" conveyed a false idea, whether applied to the emanation from an x-ray bulb or to light. It was a mere convention, owing its existence to the fact that Newton first plotted out things by rays, actually, however, waves and not rays were concerned in these phenomena. The special features about x waves as distinct from light waves which made them so interesting were, first of all, their penetrating power and different laws of absorption, which made ordinarily opaque bodies appear transparent, and secondly, the fact that the type of radiation was so extremely minute. The discovery of the very short waves emitted from an x-ray tube, said Professor Bragg, had meant to the physicists exactly what the discovery of the microscope originally meant to the chemists and biologists. It had made possible a great step forward in the investigation of the structure of matter as the microscope itself at an earlier day had done. While the microscope

enabled detailed structure to be observed on a scale smaller than the wave-length of visible or ultra-violet light, the use of x rays as the illuminating agency increased this range ten thousandfold. On the x-ray scale of wave-length the molecule had relatively a large body. Its characteristic shape was imprinted by the scattered waves and could be measured, and a picture of the molecule could be drawn, just as a drawing could be made of any small object under a high power microscope. There was nothing mysterious, Professor Bragg continued, about x-ray optics. All the methods used had their parallels in ordinary microscopical examination. So much was this the case that he could devote almost the whole of his lecture to the discussion of some properties of the microscope, and at the end make the necessary qualifications for the fact that instead of looking at an amoeba under the microscope one was looking at a molecule by means of x rays. There was this difference, of course, that in the case of the microscope the final recording instrument was the retina, whereas in x-ray optics a more indirect method had to be employed. But this difference was not fundamental, the main feature, common to both processes, was the discernment of the form of a minute body by noting the way in which a beam of light fell upon the object and was scattered by it, just as a stone thrown into a pool caused a scattering of ripples on the surface, from the pattern of which rippling certain information about the projectile and its place of impact could be deduced. About fifty years ago Abbe in Germany formulated a treatment of the resolving power of the microscope which now turned out to be equally good for the new science of x-ray optics. Abbe considered cases where a body with a series of fine regular striations, or a reticulated pattern such as that of a diatom, was placed beneath the objective and illuminated with transmitted parallel monochromatic light. He showed that the scattered light formed a series of interference maxima or spectra just behind the objective, which spectra acted in their turn as sources of light, sending out waves which crossed and interfered with the image-plane of the microscope. These waves gave certain information about the form of the body concerned, and built up the visible image. The image was never a perfect one, and the fewer the spectra which could be got into the objective the more vague and diffuse it was. With every fresh order of spectra admitted the image became sharper. It was as if, said Professor Bragg, the light was asked to paint a picture of what was under the objective, but to do so with something which was the equivalent of a scrubbing-brush, with each new order of spectra which could be brought in, a tool of increasing fineness was made available, and the picture accordingly became more detailed. All this corresponded with the infinitely more minute observations in x-ray optics, except that, in x-ray examination, the microscope was, as it were, cut short at the region where the spectra were formed, and as physical conditions made it impossible to coerce the spectra into recombining to form the image, the spectra had to be measured by suitable instruments, and the image built up by calculation. Thus although images of atoms and then molecules could not be formed directly, devices could be used to show what the images would be like if one could see them and Professor Bragg exhibited a series of such "photomicrographs" of atomic arrangements, which, he said, if the element of calculation might for the moment be neglected could be regarded as x-ray photographs of ultimate matter with an enlargement of many thousand million diameters. Major C. J. S. Phillips, in moving a vote of thanks, said that this work which already had many laboratory and industrial applications might not be without its medical interest also opening up the possibility of discerning finer differences in tissue structure than the microscope could reveal.

THE DURATION OF PREGNANCY

METHODS of calculating the date of parturition are at present admittedly unsatisfactory, and any attempt to trace the laws which govern the duration of pregnancy deserves careful consideration. In the summer number of the *Journal of Obstetrics and Gynaecology of the British Empire* W. A. Jolly, professor of physiology in the University of Capetown, has submitted clinical evidence that the period of human gestation is intimately related to the length of the mother's menstrual cycle in any particular case. He concludes that the physiological period of gestation extends over eleven cycles, counting from the middle day of the last menstrual flow, and not over ten cycles as is generally assumed. He believes that this constitutes a law in those pregnancies in which the maternal cycle is short. When the cycle is one of twenty-four days, and regular, the pregnancy, counting from the last menstrual flow, lasts for 264 days—that is, eleven cycles. The actual period of gestation, reckoning from the fourteenth day of the cycle (when ovulation and conception are assumed), is 252 days—that is, ten and a half cycles. Again, when the cycle is one of twenty-six days the corresponding figures are 286 and 273 days. When the cycles are longer the law is modified by a complication resulting from the age of the foetus, and birth is likely to occur when the tenth missed period following conception falls due, or shortly afterwards. In the human female the twenty-eight-day cycle is usual, and the data in textbooks apply directly to this case. Professor Jolly remarks that, in view of the admitted fact that parturition commences on an average about ten cycles after the last menstruation, it may seem at first sight unreasonable to deny that this represents the physiological law of gestation and to deduce a law from short-cycle cases which are relatively rare. When, however, account is taken of the great variations in the duration of human pregnancy, the considerable difficulty in accurate prediction of the date of birth, and the manner in which this date is affected by extraneous circumstances, it becomes evident that a complication exists for which allowance has not been previously made. He suggests that the length of the cycle may have tended to increase in course of time in the human race, in consequence of this the increased age and size of the foetus lead in many cases to uterine evacuation before the "endocrine clock" is ready to strike. The evidence submitted by Professor Jolly in support of this interesting view is certainly worthy of critical examination, and further investigation along these lines should yield results which the clinician as well as the physiologist will be glad to have.

INFLUENZA AND THE ONSET OF ACUTE PSYCHOSES

THE frequency with which mental disorders and diseases of the central nervous system follow epidemics of influenza has been noted on various occasions, and particularly in the serious outbreak in 1918-19, which led Sir George Savage to conclude that of all the infectious diseases influenza was most likely to have mental sequels, though this type of mental disorder pursued generally a favourable course. In the October issue of the *Journal of Neurology and Psychopathology* T. C. Graves remarks that the most dangerous age for influenza in this respect is early youth, and that other critical periods are those of the puerperium and the climacteric. It appears to be generally agreed that the character of the influenzal attack bears no relation to that of the ensuing psychosis, and that there is no correspondence between the extent of the pulmonary affection and the severity of the mental symptoms. Apart from the lungs, other regions of the respiratory tract may become involved in influenza, and the infection may especially affect such cavities as the nasal sinuses and middle ear, which lie inside the skull and are adjacent to, though outside, the immediate brain case. The influenzal sym-

ptoms displayed by a normal person may differ considerably from the symptoms in patients with chronic septic processes in the head. After the primary influenzal attack has come to an end the infective process may persist in a chronic form, and give rise to pathological changes in other parts of the body. Graves recalls that, during the epidemic of influenza in the first quarter of 1927, many patients suffering from acute psychosis and presenting influenzal histories were admitted to mental hospitals, through the remaining months of last year, and only in 1928, patients continued to be admitted with clinical histories clearly traceable to the epidemic. He divides acute influenzal psychoses into two groups, according to whether the sequel is immediate or delayed. He recognizes, further, three types of those cases in which the onset of the psychosis is in close relation to the influenzal attack. In the first type there is a predominant and profound general toxæmia, in the second there are pronounced mental symptoms and toxæmia, in the third the mental symptoms predominate.

BCG THE NEED FOR STATISTICAL INQUIRY

THE medical short story that follows might have been headed "The mystery of Denise D." This puzzling French child was born at Châteaubourg, near Vitré, Ille-et-Vilaine, on August 26th, 1926. Within ten days of her birth she swallowed, on the recommendation of Dr. F. Pantrel, three doses of BCG at the intervals prescribed by Professor Calmette. It does not appear that the family of Denise D. was prone to tuberculosis, but doubtless Dr. Pantrel was impressed by the fall in the general mortality of infants which is said to follow the ingestion of BCG. In February, 1927, Denise D. was smitten with an attack of impetigo, combined with adenitis in the glands of the right side of the neck, and her mother, having transferred her allegiance from the doctor at Châteaubourg to a chemist at Vitré, called in a surgeon, who performed an extensive removal of the inflamed glands. Shortly afterwards the condition of the infant became worse, and in December, 1927, she died. Four months before the death of Denise D. her mother gave birth to another child, Marie. Although Marie did not ingest BCG, in January, 1928, she also had suppurating glands in the neck. These do not seem to have required surgical intervention, and it is reported that Marie is now on the road to recovery. It happened that Professor J. Lignières, a veterinary surgeon of Buenos Aires, who professed great admiration for the work of his dear colleague in the Académie de Médecine of Paris, Professor Calmette, was looking around for evidence to show that the dear colleague's BCG was dangerous to the human organism. He had already discovered a leprosy doctor who had succumbed after trying to cure himself with BCG, but in this case not much had been done in the way of bacteriological investigation. In the case of Denise D. the chemist of Vitré conceived the idea of preserving some of the pus in sterilized tubes, and this, as also some pus from the glands of Marie, was mixed with distilled water by Professor Lignières in June of this year, and injected into guinea-pigs. Both samples of pus contained large numbers of acid fast bacilli. When the guinea-pigs were killed they showed no sign of tuberculous lesion, but the professor, while admitting his difficulties in separating the acid-fast organism from the masses of cocci which were also present, was satisfied that the organism in the glands of Denise D. was the *Bacillus Calmette-Guérin*, and that Marie was infected with this organism by her sister. Some portions of this chronicle of the D. family were presented to the Académie de Médecine by Professor Lignières last July, but his charges failed to draw an answer from Professor Calmette. On October 23rd, however, Professor Lignières returned to

the attack, aimed with slides and descriptions of the deceased guinea-pigs. Incidentally he expressed himself as hurt that his learned colleague Professor Leon Bernard, vice-president of the Health Committee of the League of Nations, had forgotten to invite him to the international discussion of BCG by that body. Professor Bernard denied that he was vice president or responsible for the invitations, and Professor Calmette replied to the rest of the charge. It appears that Professor Calmette also obtained some of Denise D's pus in October, 1927, and in January, 1928, he was supplied with some pus from Marie D. He came to the conclusion that both infants had been infected from the same source with bacilli of human type, which were only mildly virulent, and were certainly not the BCG. The latter organism had been shown to be inoffensive, even in formidable doses and if Professor Lignieres's deductions were correct the doctors who had given BCG to 110,000 infants in France would certainly have recorded a number of accidents. They had not done so. Moreover, the international conference organized by the League of Nations had, according to Professor Calmette, unanimously affirmed the perfect harmlessness of the vaccine BCG. As Professor Calmette refused to contemplate making any further answer to Professor Lignieres, it will presumably be impossible to elucidate the mystery of Denise D. It would seem, however, that out of 116,180 infants vaccinated in France with BCG since July, 1924, Professor Calmette has managed to collect records of 3,607 who were born of tuberculous mothers or brought up in tuberculous surroundings. In *La Presse Médicale* for November 7th he gives an account of the fate of these infants, from which it appears that the death rate among them was much less than among the non-vaccinated population. Professor Calmette's new statistics still seem open to doubt, and in view of the information contained in a report by Professor Léon Bernard published in the same issue of *La Presse Médicale*, there is no need to examine them further. This report deals with the findings of the conference promoted by the Health Committee of the League of Nations for the investigation of vaccination against tuberculosis by BCG. The conference was attended by a large number of distinguished scientists, including Professors Madsen of Copenhagen, Bordet of Brussels, Neufeld of Berlin, Roux and Bernard of Paris, Krans and Gerlach of Vienna, and representatives from New York, as well as from many of the smaller European States. Curiously enough, no Englishman appears to have attended the conference. The result of the investigations was to show that BCG is unlikely to produce tuberculous lesions, and that it confers a certain degree of immunity. But the conference thought a request should be made to the League of Nations for expert statisticians to go into the question of the best method for collecting and analysing the mortality and morbidity tables of infants, both vaccinated and unvaccinated. We hope that the League will see its way to accept this proposal, so that if possible the dispute as to the value of Professor Calmette's method of pre-immunization against tuberculosis may be definitely settled.

THE LEAGUE AND SLEEPING SICKNESS

A second conference, arranged by the League of Nations on sleeping sickness began in Paris on November 5th. It may be recalled that the first conference was held in London during May, 1925, and references to the important discussions were made in our columns on May 23rd, 30th, and June 6th of that year. Various measures were recommended to the administrations and doctors of central African territories infested by the tsetse fly. It was urged, for example, that there should be a medical service bearing an adequate relation to the numbers of the popula-

tion and to the areas to be controlled. The institution of a uniform system of health passports for natives and the demarcation of uninhabited zones on each side of the frontiers so as to minimize frontier traffic were suggested. The conference further recommended that an international commission should be sent to tropical Africa to study various scientific problems concerning the forms of the disease, the way in which it spread, and possible remedies. This investigation was conducted in Uganda and districts round Lake Victoria between the end of 1925 and August, 1927. The commission has recommended measures with a view to controlling the disease. The second conference, at which Great Britain, Belgium, France, Italy, Spain, and Portugal are represented, is dealing with the difficulties encountered in the application of administrative measures recommended by the first conference, and with reports submitted by delegates on the methods employed in their territories. It is also considering what further investigations should be undertaken in laboratories and in the research centres of those regions of Africa which are infested by the disease. Lastly, the agenda includes a study of veterinary problems concerning the elimination of trypanosomiasis in domestic animals.

BOOKS IN ELEMENTARY SCHOOLS

THE report recently issued by a consultative committee appointed by the Board of Education "to inquire as to the selection and provision of books for public elementary schools and to make recommendations for the improvement of their quality and supply" contains several passages that will interest the medical reader. The committee has collected a considerable amount of evidence bearing upon the possible conveyance of infection through books, from the Medical Department of the Board of Education, the Pathological Laboratory of the Ministry of Health, several school medical officers in county and urban areas, and from the medical officers of three great public schools. The conclusion reached is that the risk of spread of infection from books is insignificant compared with the commoner and more important modes of dissemination of infection. Discussing the supply of bibles in schools, the committee notes that these are often printed in too small type. This is a fault we have often had occasion to deplore, inasmuch as it discourages the study of a work which, apart from religious considerations, is indispensable in the teaching of good English. In another passage we read that though the Board of Education has issued various publications dealing with physical exercises and games for elementary schools, including the *Memorandum on Physical Education* and the *Supplement for Older Girls*, as well as a pamphlet entitled *Notes on Campy*, the committee do not think that a separate book on hygiene is required for pupils in elementary schools, especially as the Board has recently issued a *Handbook on Health Education*.

THE Huxley Memorial Lecture will be delivered before the Royal Anthropological Institute by Sir Arthur Keith, M.D., F.R.S., on Tuesday, November 27th, at 8.30 p.m., in the Lecture Room of the Royal Society, Burlington House, Piccadilly. The title of the lecture is "The evolution of the human races."

¹ Board of Education. Report of the Consultative Committee on Books in Public Elementary Schools. London: H.M. Stationery Office, 1928. 1s. 3d. net.

At a quarterly meeting of the Royal Medical Psychological Association, to be held to-day (Friday November 23rd) at the British Medical Association House, Tavistock Square, W.C., at 2.30 p.m. with Professor J. Shaw Bolton in the chair, there will be a discussion, under the auspices of the General Paralysis Subcommittee, on certain points raised in papers on general paralysis read by Drs J. Brauder and J. F. Smyth at the annual meeting.

ROYAL SOCIETY OF MEDICINE

ANNUAL DINNER

THE annual dinner of the Royal Society of Medicine was held at the May Fair Hotel, London, on November 15th, when a company which must have numbered five hundred assembled under the presidency of Lord Dawson of Penn, who was supported by the immediate past-presidents—Sir John Bland Sutton, Sir William Hale-White, Sir St Clair Thomson, and Sir James Berry—and by the presidents of the twenty-five Sections. The principal guests on either side of the President wore the Right Hon Winston Churchill, M P, Mr Rudyard Kipling, Sir Ernest Rutherford (President, Royal Society), Sir John Ross Bradford (President, Royal College of Physicians), Sir Berkeley Moynihan (President, Royal College of Surgeons), Sir Ewen Maclean (President, British Medical Association), and Sir William Bragg (President, British Association). Others at the high table included Lord Ashfield, Sir Anthony Bowlby, Sir Holburt Waring, Sir George Buchanan, Dr J W Carr (President, Medical Society of London), Surgeon Vice-Admiral Gaskell (Medical Director-General R N), Major-General Fawcus (Deputy Director-General A M S), Sir Thomas Hughes (Chairman, General Council of the Bar), the Editors of the *British Medical Journal* and the *Lancet*, Dr F N Kay Menzies (Chief Medical Officer, London County Council), and the Headmaster of Epsom College.

Mr WINSTON CHURCHILL, in proposing the health of the Royal Society of Medicine, praised it for a record of service to science and humanity which held comparison with any scientific or similar body in the world. In contemplating its history, which extended back to the year of Trafalgar, he was impressed by the formidable march of knowledge. Lord Balfour, on his eightieth birthday, reminded his audience that it was the ambition of Bonham to live until he was eighty that he might read every book worth reading in the world—in the early nineteenth century not an unreasonable ambition. But since that time human thought had unceasingly expanded. It would be futile now for anyone even in a single branch of science to attempt to master every valuable work bearing upon his subject. It was because of this increasing knowledge that such bodies as the Royal Society of Medicine had acquired a vital and essential position in the intellectual and practical life of the community. There was an increasing need for focusing and combining the results of human study in the different branches. "We have to be sure that the furthest point reached by the most adventurous patrol at dusk is entrenched and occupied before dawn by the whole army."

The Chancellor of the Exchequer went on to say that he must not be expected to lay down the law on the subject of medicine. "I have tried my hand on a good many things, but I am not going to poach on your preserves. Your task is too difficult, but I can understand how difficult it is, because in its continual contact with unknown factors it resembles in a good many respects the political profession with which I am more or less acquainted." Every human being might be likened to an empire, embracing innumerable populations, of different races, covering a vast province holding different conditions of pressure and climate, and usually in a state of internal or external war. As long as the presiding genius in the shape of the central governing control was seated firmly on its throne there was order throughout the complex mechanism, but when that central control began to weaken or to age or was upset by any cause, sudden or gradual, then disorders, discontents, riots, mutinies, revolutions broke out, and the story of the decline and fall of the Roman Empire or of the Russian Empire of recent memory was repeated. In politics several of the diseases with which medicine was grappling had their parallels. Communism the Chancellor likened to cancer—the revolt of a single cell, subverting and corrupting those immediately around it, establishing a foreign principle of life within the body politic, manifested by the most violent symptoms and requiring remedies about which there was much difference of opinion, some said the knife, but all were agreed that the remedies

must be prompt and drastic. The resources of invention which could be employed in the treatment of disease were growing, but so was the variety of conditions requiring treatment. He looked upon the Royal Society of Medicine as a sort of League of Nations, bringing co-operative effort to bear upon the disordered state. He paused to point out how much had been achieved by medicine in every experience of daily life, in every development of imperial work, the advance of medicine played a noteworthy part. Having served at the Colonial Office on two occasions, separated by a long interval, he had seen something of the great advance in tropical medicine which had eradicated from immense territories the diseases by which they had been for centuries tormented. Marvels had been wrought, and these were only an earnest of what the future had in store. However great the achievements already performed in the medical sphere, and whatever substantial results those in the political field might be able to show, both were asking for more, and expecting better results in the future. Politicians looked to the medical profession to lay its hands on a great many of the evils of modern life which caused them a vast amount of worry at the present time.

In conclusion, Mr Churchill said that, having dealt with the troubles of the medical profession in dealing with human bodies and those of politicians in dealing with the body politic, he would utter one word of advice to the "patients" who were not represented on that occasion. He would urge the patients not to be in too much of a hurry to change trusted and sober-minded advisers for the latest quack who came in with some potent cure or specific to sweep away the evils which had racked mankind since the dawn of time. He had spoken as one who had the sincerest admiration for the medical profession, whose activities he had witnessed in war and in peace. "With my own eyes, at little more than the distance across this room, I saw, in South Africa, a doctor gain the Victoria Cross. I know how nearly the role of the medical profession corresponds to that of a self-sacrificing priesthood in its devotion to causes and humanities which in this world bring no material reward."

Lord Dawson, in responding to the toast, after expressing his appreciation of the Chancellor's speech, said that he would not tarry over the internal affairs of the Society except to say that, with its many component Sections, it continued to grow in wisdom, stature, and comprehensiveness. Among other illustrations of the trend of medical thought and the spirit of its service, Lord Dawson made a reference to anaesthesia, suggested by the discovery by Mr C J S Thompson that, in the year 1827, a young doctor named Hickman produced anaesthesia in animals by inhalation of CO₂ and N₂O, performed painless operations upon them, and brought his results to the notice of the medical professions in England and France, trying to persuade them to institute the same anaesthesia for man. Coming to more recent events, Lord Dawson touched upon the Harveian tercentenary, and recalled the acclamation given to the Russian genius Pavlov, a heroic figure indeed, who had kept the lamp of knowledge burning through war and revolutions. He next recounted the tragic adventure of the commission of inquiry into yellow fever, which involved the deaths from infection successively of Adrian Stokes, Noguchi, one of Japan's great sons, and William Young. Linked with these great names for sacrifice he mentioned Robert Knox, who had not, indeed, perished on a tropical coast, but had doubtless shortened his life, full of happy work and friendship, as a result of his absorption in the study of radiology, of which he was a pioneer and leader. All these men represented the spirit of service in medicine.

After pointing out that the steady move of medical thought was towards the threshold of disease, that medicine was passing from the age of acute to subacute infections in which the state of the host counted as a greater factor, and that future thought would be occupied with forces rather than with lesions, with the dynamic rather than the static, Lord Dawson in a lighter vein contrived to draw a further parallel between medicine and politics by a reference to the four Hippocratic humours. The blood,

he said, was the prime of ministering humours, which was propelled by a great heart and permeated and held the other humours. The phlegm, in its parliamentary equivalent was that force which begot ideas, and penetrated everywhere, even into the taxpayer's pocket. Then there was the yellow bile, to which humour a group of statesmen had paid such homage as to name their official boot after its colour. Finally, there was the black bile, which took origin in the spleen, a "red" organ, useful in health, but at times becoming overgrown and swollen, and seeking to destroy good blood, in which circumstances the spleen was removed and the body got on quite well or even better without it. He also placed at the disposal of Mr Churchill the secret of nature that these humours were seasonal in their influence, that the blood and the phlegm were at the height of their power in the month of June, whereas the bile humours gained the ascendancy in the late autumn.

Lieut Colonel W. P. MacArthur, D.S.O., in a most felicitous speech, proposed the health of "The Guests." He spoke of Mr Churchill's versatility—statesman, journalist, author, soldier in the field, artist of no mean merit, and bricklayer! As for Mr Kipling, Colonel MacArthur told how, many years ago, he took the perfect story of how the fairies forsook England, translated it into Gaehe, and recited it to a fisher audience in the ultimate island of Tory. Such was the response of the audience to the ancient magic recaptured by Mr Kipling's artistry that even the author himself would have been moved, weaned though he must be with the plaudits of his admirers. As for the rest of the company at the high table, they might be likened to that company of Chaucer's time who assembled at the Tabard Inn in Southwark, including the doctors of "physik," unrivalled "to speke of physik and of surgerye," and in every branch of their art "verray parfit praktisours," also the generous benefactor of medical research who, like the Clarke of Oxford, having earned a golden pipe, "on bookes and on leynge he it spente," the man of law "war and wys" and of great reverence "for his science and for his high renown," and finally the leaders of the press, who might be likened to the host of the Tabard, busy in repressing the over-uberant, encouraging the worthy, and generally shepherding the flock.

Mr Rudyard Kipling responded to the toast.

[With regard to Mr Kipling's speech the press representatives were informed on arriving at the dinner that copies of the speech had been sent by Mr Kipling's secretary to the Associated Press. It was afterwards discovered that on the copies there was an intimation to the effect that the copyright reverted to Mr Kipling two days after the delivery of the speech. This unusual course—stated by one authority on copyright matters to be unprecedented—prevents a weekly journal from publishing any considerable extract.]

Mr Kipling's speech was on the theme of Nicholas Culpeper, the astrologer-physician of the seventeenth century, who diagnosed a case by erecting a horoscope and inquiring of the face of the heavens. Mr Kipling suggested that Culpeper, if he returned to earth to-day, would still be at ease in the medical Sion. He had believed in the transmutation of metals, but he could still be shown that in full blast at a Royal Society soirée. Nor would he be astonished to see men snatch out of the air an influence or humour of which they knew nothing more than that it lighted, warmed, and worked for them, and transmitted their speech and vision from one side of the world to the other. The news that unknown influences from the skies lashed and tore through all matter everywhere and at all times would be received by him with perfect calm. He pictured Culpeper visiting Greenwich and the B.B.C., and finding some confirmation of his own early speculations, and finally he asked some questions of those present. Was it not likely that the multitude and significance of the revolutions that had been heaped on mankind during the past few years had made men, in self-defence, specialize more and more narrowly? Had they not been driven headlong to abandon their conceptions of life, matter, and motion, and was it not human that in that upheaval men might have carried off each his own cherished prepossession and camped beside it just as refugees did after an earthquake? Was it not arguable, then, that they might be still mistaking secondary causes for primary

ones, attributing to instant and visible agents of disease unconditioned activities which in truth depended on some breath drawn from the motion of the entire universe? At some future time, when the bacteriologist and physicist were for the moment at a standstill, the problem might be taken to the astronomer and the question of Culpeper—of course in modern scientific language—put to them. "What was the aspect of the heavens when such and such phenomena were observed?"

Mr FURST BIRMINGHAM, O.M., P.R.S., also responded to the toast. Alluding to his own efforts to teach physics to generations of medical students, he said that when he recalled the raw and restive groups to which he had lectured, and then looked round that banquetting hall and beheld the resulting product, he felt that something more wonderful than the transformation of radium had occurred, and something which must have involved much more energy in the process. Until some fifty years ago the medical profession was in a sense complete within itself. It advanced only by the accumulated experience of its own adherents. Then there began a change which had greatly influenced these latter days of medicine—namely, the application to medicine of scientific methods and the growth of the ancillary sciences, including physiology, bacteriology, and, more recently, biochemistry. This had led to a multitude of discoveries and to great advance. Within the last ten years especially had numbers of men been set aside for research into the problems which lay at the basis of medical practice. He mentioned in this connexion the work which the Medical Research Council was doing, also the Imperial Cancer Research Fund, the Otto Beit Trust, and the Rockefeller Foundation at University College Hospital and elsewhere. The Royal Society also had endeavoured to do its best by founding the Fullerton professorship, and in other ways to assist the scientific side of medicine. He was sure that all this was only a beginning. He foresaw the time when much more help would be available to extend in a multitude of directions the scientific work ancillary to medicine. Those present knew better than he how relatively little had been done and how much territory remained unexplored. He looked for an increasing international attack upon the problem of disease in general. Even from the purely economic point of view, disregarding the human, it would be many times worth while. It seemed to him that the medical domain was almost the only one left to science for the pursuit of its dreams and visions. Twenty or thirty years ago, if a company of intelligent men and women had been asked what it was they most wished to see fulfilled in their time they would have replied variously, saying that they desired such things as had been since fulfilled in aviation, wireless, television, and the like. It was difficult to say what remained for mankind to wish for, with the great exception of health, and more health, and the happiness which it brought, and it was the medical profession alone which was in a position to give that guerdon to humanity.

SOCIETY OF MEDICAL OFFICERS OF HEALTH

ANNUAL DINNER

THE annual dinner of the Society of Medical Officers of Health was held at the Piccadilly Hotel on November 15th, with Dr J. HOWARD-JONES of Newport, Mon., President of the society, in the chair, the principal guests being the Right Hon. H. P. MACMILLAN, K.C., Chairman of the Lunacy Commission; Dr H. B. BRACKENBURY, Chairman of Council of the British Medical Association; Dr Andrew BALFOUR, Dr Catherine CHISHOLM, President of the Medical Women's Federation; and Mr Henry LESSER, President of the National Association of Insurance Committees.

Mr H. P. MACMILLAN, in proposing the toast of the society, said that he welcomed the opportunity of expressing—what all people engaged in public health felt—a sense of indebtedness to the medical officer of health for the work he performed in the public interest. Since the days of Disraeli the developments that had taken place in public

health administration had been nothing short of revolutionary. He had tangible evidence of that recently, when the representatives of one of the leading insurance companies asked him the surprising question whether, within their constitution, they could reduce their life premiums. They informed him that the expectation of life had been so greatly increased in consequence of modern sanitation and public health administration that they were in a position to discard the mortality tables which formerly ruled and to quote lower premiums to those who desired to insure. The country was suffering from many disadvantages and embarrassments as the result of the war, but at least it was possible for them to congratulate each other on the fact that the people in general had benefited enormously of recent years as the result of public health legislation and administration. It should be a principle of such administration, however, not to do everything for the people, but to teach them to do things for themselves. People must be taught how to face up to their responsibilities, and how best to utilize their lives and improve their conditions. Mr Macmillan said in conclusion that it had been his own good fortune to be associated with many medical officers of health and with numbers of other medical men on various public bodies, and he yielded to none in his admiration for their work. To medical officers the lucrative prizes of the profession might not come, but they had the greater reward, which was the result of public duty—the reward of a happier and better community, more suitably housed, healthier, and economically more prosperous.

The PRESIDENT (Dr Howard Jones), in responding, referred to the birth and growth of the society. It had now thirteen branches, extending to the South of India and the Malay States, and also six groups concerned with special departments of its work. Dealing with the cost of public health services, the president said that in a recent year, out of the total sum spent in administration by local authorities, only about one-thirtieth was spent on the services usually controlled by medical officers of health. Referring to the exchange visits of public health officers effected under the auspices of the League of Nations, he said that this had probably brought about more good fellowship among the nations than any other department of the League's work, he understood also that the medical officers of other European countries who had visited Great Britain had returned to their homes with a profound respect for the public health work of this country.

Dr CHARLES PORTER proposed the health of the guests, to which several responses were made.

Dr HADEN GUEST referred to the Government's de-rating bill and the far-reaching changes which it would bring about in local government, making an appeal to medical men and women to play a larger part in national and local politics, because in his view scientific ideas and the scientifically trained mind were greatly needed in legislation and administration.

Dr BRACKENBURY spoke of the cordiality which pervaded the relations between the society and the British Medical Association. It seemed to him that the distinction between curative and preventive medicine was growing less sharp. Members of the profession, no matter in what branch they were engaged, had had the same training, and the medical officer did not cease to be influenced by his clinical training when he took up his future work, any more than the general practitioner or the specialist. The distinction between clinical and administrative work was also becoming less sharply defined. Medical officers of health were first appointed to diagnose and treat the diseases of the community, which also had been considered to be the primary object of the ordinary practising member of the profession. Later, however, it had become clear that in diagnosing and treating such illnesses they were all actually practising preventive medicine. He hoped that his presence in a representative capacity on that occasion would be regarded, as it was meant to be regarded, as an earnest that members of the profession generally adopted the same attitude, and were uniting to effect the improvement of the health of the community.

Mr H. LESSER urged the need for a more complete liaison between national health insurance bodies and medical

officers of health. What eventual form such co-operation might take it was difficult at present to say, but by its health propaganda and by assisting to consolidate the efforts of the various bodies concerned in public health, the society was rendering very important service. The Mayor of Newport (Mr Walter Griffiths) spoke of the high esteem in which the president of the society was held in Monmouthshire, especially for his establishment in Newport of a very fine maternity and child welfare organization, the work of which was linked up with the health services of the educational authorities. The president's health was pledged at the instance of Professor H. KERR, and with Dr HOWARD-JONES's brief reply the proceedings were brought to a close.

A PRIVATE HOSPITAL SYSTEM:

THE SHANGHAI EXPERIMENT

[FROM A CORRESPONDENT]

In the practice of modern medicine and surgery it is being found to an increasing extent that patients, especially if acutely ill, stand a much greater chance of recovery if treated in hospital. Ionization, actinotherapy, vaccine and serum therapy, the urgent treatment of complications, and methods of more accurate diagnosis all demand closer supervision and more suitable surroundings than can be provided in the home. In America this seems to have been recognized to a greater extent than in England, where the upper and middle classes have restricted facilities for entering the large hospitals, and have to depend mostly on private nursing homes. As a rule, nursing homes often lack the complete equipment that is necessary, and, by their nature, are being run as a source of profit to the owners, the cost is higher than many middle-class people can afford. There should be room in every city of any size for at least one private hospital, complete with all departments for every kind of treatment, where patients can continue in the care of their own medical practitioner. Such a hospital depends entirely on the goodwill of the profession, for doctors are often reluctant to send their clients to an institution where the case would pass out of their hands.

In these days of motor cars and telephones it rarely happens that a doctor can remain long out of call to his patient. Patients know this, and benefit by the peace of confidence they regard themselves as being in a hotel for the sick, with a known tariff, they have no uncomfortable feeling that they are taking advantage of the charitable subscription list.

It would, of course, be desirable that a private hospital should open its doors free of debt, and there is here an outlet for philanthropic citizens to benefit their fellow men, but, as has now been shown in the United States, it is not impossible for a hospital to support itself and provide for the sinking fund while restricting its charges sufficiently to bring them within the scope of ordinary purses.

During the summer of 1926 Mr C. E. Rayner, who was retiring from business life in Shanghai, built and equipped an institution known as the Country Hospital, which he presented to the International Settlement anonymously, though his name has since become known. It cost £300,000, and embodies all the features (some of them on a lavish scale) of a modern hospital of 125 beds. By the deed of gift the donor intended it to be run on business lines like a hotel, but owing to local and abnormal causes there has been a deficit, which has been met out of municipal funds. The prospective benefit to the community was such that the Shanghai Municipal Council had no hesitation in guaranteeing the bank that any overdraft would be met.

With the exception of two free wards, male and female, endowed by the donor, the hospital deals with three classes of paying patients. Those in the first class have separate

private rooms, each with a bathroom, second class rooms have two beds, with a bathroom; and third class patients are accommodated in six-bed wards. The charges are 30s 15s, and 8s per diem respectively, these include food, nursing, drugs, and all the benefits of comfortable furnishing and complete equipment.

There is a suite of operating theatres, and radiological, hydrotherapeutic, and ophthalmological departments, retinotherapy, electric massage, and Zander Institute treatments are available. The clinical laboratory gives results as promptly as possible, and there is a well-equipped pharmacy. The kitchen, at the top of the building, is in charge of two qualified dietitians, who ensure that every diet is exactly as ordered by the patients' doctors. By its own mechanized laundry a plentiful and ready supply of clean linen is ensured, and the general works (heating, lighting, etc.) are looked after by a resident engineer.

The ratio of nurses is one to every three patients. The sisters are international, and possess the diploma of the

any change in his patient, and, should any complications set in, the superintendent is available for emergency treatment. In practice, however, it hardly ever happens that the patient's own doctor does not arrive in time to deal with the matter himself. No patient is admitted unless by his own doctor's order, should anyone arrive without this he is asked to nominate a medical man, and the superintendent can help by impartially suggesting names that he may deem most suitable.

Professional fees are arranged between the doctor and patient as in nursing homes in England, doctors arrange for their own consultants. A moderate fee is charged for operation room expenses, the surgeon walks in to find everything, from instruments to gloves, provided for him.

By these methods the medical profession in Shanghai feels it has in the Country Hospital a very great convenience for proper treatment and every doctor is therefore more or less an outdoor agent. It has been observed that

The Main Entrance.

The Reception Hall

hospitals of the country from which they come. The probationer nurses attend a course of lectures given by doctors on the visiting staff, and can qualify by an examination, which is of a standard approved by the General Conference of Nurses. The radiologist is resident, and available at all times for emergency examinations.

The hospital is administered by a resident medical superintendent, who also acts as executive secretary to a board of governors, this board of public men meets regularly, and keeps in touch with the best methods by which the hospital can meet the public interests.

Any general practitioner who wishes to have his patients admitted must first submit his name and credentials to the superintendent, who then places his name, if found satisfactory, on a list, this is especially necessary in Shanghai, where there is no registration and where degrees and diplomas are of varying quality. The fact that a doctor has his name on the visiting list gives him an added interest in the place.

Every patient on admission has to provide a guarantor, rarely is any difficulty found in this respect, and it is of great use in helping to keep free of bad debts. The care of a patient remains wholly in the hands of the private practitioner concerned, and the hospital activities are confined to nursing and to seeing that individual instructions are obeyed. The doctor is informed by telephone of

patients seek admission much more readily when they know they are to remain under the care of their own doctor.

With regard to income, the following figures, at fees much the same as those in the Country Hospital, give the computation of earnings in an American private hospital.

14 private rooms at \$7.50 — 85% occupancy	\$32 576.25
20 two-bed rooms at \$5 — 85% "	31 025 00
9 four bed rooms at \$4 — 85% "	11 169 00
Operation room fees at \$20 and \$15	13 616 00
Special nurses	8 500 00
Total	\$96 886 25*

*Equivalent to £19 377 sterling

The whole difference between an institution such as this and an ordinary nursing home lies in the much wider facilities that a hospital can offer. If in the hands of a capable administration there need be no call for appeals to charity, while at the same time not only the local medical profession, but patients too, who dislike the lack of privacy in a public hospital, are catered for. A point of importance in the erection of such a hospital is the necessity for providing a nurses' hostel in the vicinity, for this greatly adds to the amenities of a nurse's life and makes the staff contented.

Such a system might well be introduced into England and be further extended.

PUBLIC HEALTH CONGRESS IN LONDON

SINCE 1920 a Public Works Congress and Exhibition has been held biennially in London. Its promoters have been urged to widen its scope to include public health interests, but the programme has been too fully occupied. Therefore it has been decided to arrange, probably in alternate years, a similar congress and exhibition dealing with public health and sanitation. The first such event, organized by a committee under the chairmanship of Sir Frederick Willis, and including representatives of the Ministry of Health, the County Councils Association, and other bodies, has been held at the Agricultural Hall, Islington, during the present week. Eight hundred delegates, from 350 local authorities and from a number of voluntary societies, took part in the proceedings.

Mr NEVILLE CHAMBERLAIN, Minister of Health, who attended the opening function, said that this was an interesting moment in the history of the health services. Those services were comparatively of recent growth, but they had attained in the estimation of the public an importance and value quite remarkable. The fact that the British population was still increasing was due to the improvement which these services had effected in the death rate, otherwise, with a falling birth rate, the British would now be a dwindling stock. Some obstinate problems still remained, as was shown by the 30 million weeks' work lost through sickness in 1927 by the insured population alone. The Minister, in a reference to the new proposals for local government which he was shortly to introduce into Parliament, said that one of the considerations had been the opportunity of getting a better return in health services for the money expended by making one authority responsible for such services in each area, instead of two, so that the single authority could make a proper survey of health needs, and rearrange and classify its institutions, utilizing some perhaps for a different purpose from that which they had hitherto served, closing altogether some which were hopelessly out of date, and working throughout, he hoped, in full co-operation with voluntary hospitals.

At a subsequent session Sir GEORGE NEWMAN, in speaking on the purpose of the public health service, traced four great stages in its evolution. The first was land drainage and agricultural development in order to avoid pestilence and famine, the second was the institution of by-laws for securing cleanliness and dealing with infection in cities, the third was marked by attention to environment, and the fourth, following largely the discoveries of Pasteur and Koch, by attention to the problem of personal hygiene. Sir George went on to show how medicine had captured for its own purposes many non-medical agencies and powers, and how the medical services were increasingly using science and invention for maintaining the life and health of the community.

Sir WALTER FLETCHER also addressed the delegates on research in relation to public health. He pointed out that there must be a certain lag arising out of differences between the nature of research and public health administration, the investigator was necessarily critical and aggressive, while the administrator longed usually for peace and uniformity. The lag was due partly to the imperfection of the parliamentary machine or the exigencies of political life, partly also to social customs and prejudices, and perhaps to the wrongheadedness of cranks and fanatics. He described the progress made in bacteriology, the rise of which had coincided with the first coherent efforts of the legislature in the direction of public health services. All the great triumphs in public health work had depended largely on bacteriology. It was curious to remark the variations in the success with which the policy of immunization had been applied in different areas. In Scotland the number of persons immunized against diphtheria was twice the number immunized in England and Wales, and, in proportion to the population of the two countries, eighteen times the number. Sir Walter Fletcher also spoke on industrial hygiene, expressing the hope that the progressive industrialization of native races in our African and Asiatic empire would not be mismanaged, as was our own industrial revolution, from the hygienic point of view.

With regard to national fitness, there was a disposition to assume that things were better now than they were shown to be by the national service recruiting during the war, but the recruiting statistics for the fighting services still caused grave disquiet.

Other subjects of discussion during the week were the housing problem, the national milk supply, food protection, hospital construction and equipment, water pollution, and sewage disposal. More than a hundred commercial exhibiting firms occupied the floor of the Agricultural Hall.

Lectural Dinner

On the evening of November 20th a banquet was held at the Savoy Hotel. Sir FREDERICK WILLIS presided, and among his supporters were Sir Arthur Robinson, the Right Hon. H. P. Macmillan, K.C., Chairman of the Lunacy Royal Commission, Lieut-General Sir Matthew Tell, Mr L. G. Brock, Sir Robert Robertson, F.R.S., Surgeon Vice-Admiral Gaskell, Air Vice-Marshal Munro, Dr Hubert Bond, Sir Walter Fletcher, and Sir Henry Keith. Proposing the toast of "Parliament," Mr MACMILLAN paid a high tribute to the work carried on in the committee rooms, and made special reference to the improvements which had been effected in this way in public health administration. Replying to the toast, Dr VERNON DAVIES, M.P., delivered an interesting speech, in which he touched intimately on the various experiences of Members of Parliament, and discussed the attributes they required. Sir HENRY KEITH, with many deft Scottish touches, proposed the toast of "The Public Health Services," and referred particularly to the way in which these Services might be concerned in projected legislation. He was convinced that a great future lay before public health administration, which was still only in its infancy. With skillfully interwoven stories of Abordonian flavour he relieved any tension aroused by a trace of political bias in some of his remarks. Dr W. M. WILSON, medical officer of health for the City of London, responded briefly, and spoke of the extent of the ground covered by the Public Health Services. He indicated the ideals which were being pursued and which prompted them to continuous activity. The toast of "The Chairman" was proposed by Sir EDMUND BARNARD, who in a clever speech touched delicately upon some points which had been previously raised and spoke warmly of the work done by Sir Frederick Willis. The toast was received with musical honours, and the chairman, in replying, described how the congress had taken its origin in a desire to bring together more intimately the scientific and mundane sides of public health activities. He mentioned his personal connexion with the Local Government Board, and quoted a recent remark of Mr Neville Chamberlain, that the Public Health Department was the most important of all. He paid a high tribute to the work of Mr Warner Terry in connexion with the congress organization, and added that it was hoped eventually to use any financial proceeds resulting from such congresses for the advancement of research.

ROYAL MEDICAL BENEVOLENT FUND

SUBSCRIBERS and donors to the Royal Medical Benevolent Fund are asked to forward their subscriptions for the current year before December 31st. Not only the scope of the Fund's work, but also the amount of assistance given, depends upon the subscriptions received, and in view of the many cases in which help is greatly needed especially during the winter months an urgent appeal is made for contributions. Cheques should be sent to the Honorary Treasurer, 11, Chandos Street, Cavendish Square, London, W.1.

At the last meeting of the committee forty two applications for grants were considered and £704 was voted to thirty eight applicants. The following were some of the cases relieved.

Widow aged 62, of M.B. Since the death of her husband in 1915 the applicant has been entirely supported by her elder daughter who was on the wage. This daughter died early in September 1928, after a short illness leaving her mother without means of support. Voted emergency grant of £10 and a yearly grant of £36 in four instalments. Other medical charities have been approached to augment the widow's income.

Widow aged 65 of M.R.C.S. Left penniless on her husband's death in 1920. This daughter is earning £2 10s. a week which is the only income for these three persons. Voted £36 in four instalments. Daughter aged 32, of L.R.C.P. Living with her brother who is able to earn only 47s. 10s. and lives rent free in three rooms. On many occasions it has been found that the applicant was practically starving. Voted £25 in four instalments, clothes to be supplied by the Guild. The local Council of Social Welfare is interested in this case.

Ireland.

Vital Statistics of Northern Ireland

THE sixth annual report¹ of the Registrar-General for Northern Ireland, which has now been published, contains the vital statistics for the year 1927. It is intended in the next annual report to show death rates adjusted for sex and age distribution according to the census of 1926, the final reports on which will shortly all be published, the rates given for 1927 must therefore be regarded as subject to the limitations necessarily attached to crude rates. The enumerated population from the census of 1926 was 1,256,561, and the estimated population in the middle of 1927 was 1,251,000. Registrations in 1927 show that the marriage, birth, and death rates are all slightly below the 1926 levels and considerably below the averages for the ten years 1917-26 inclusive. The birth rate per 1,000 of the estimated population was 20.7 in 1917, and rose to the exceptionally high figure of 25.9 in 1920, since then there has been a relatively steady decline, the rate of 21.3 last year compares with 22.5 in 1926, and an average of 22.8 for the years 1917-26. At 14.6 per 1,000 the 1927 death rate is 2.0 below the average for the preceding ten years and 0.4 below the rate for 1926, the next lowest figure since 1917 was recorded in 1923, when the rate was 14.9. In the course of this period the rate has shown considerable fluctuations, rising to 20.6 in 1918 and being at its lowest last year. The principal causes of death, and the percentage of each group to the total of deaths from all causes, were heart disease, 13.9, tuberculosis (all forms), 9.7, cancer, 8.1, pneumonia, 6.9, bronchitis, 6.1, cerebral haemorrhage, 6.0, influenza, 4.1—these diseases accounting for over 50 per cent of the total. Since 1918, when the death rate from all forms of this disease was 2.54 per 1,000, the tuberculosis death rate has generally shown a downward tendency, and a further reduction last year brought the figure to 1.41. In 1927 more than 50 per cent of the deaths at ages 15 to 25, and 40 per cent of those at ages 25 to 35, were attributed to tuberculosis. The cancer death rate of 1.18 per 1,000 in 1927 showed a slight increase over the previous year's figure, and is the highest yet recorded in Northern Ireland. Deaths from measles, influenza, and respiratory diseases were below the average for recent years. Infant mortality rates showed an improvement, deaths under 1 year per 1,000 births registered being 77.7 in 1927, as compared with 84.9 in 1926 and an average of about 88 for the ten years 1917-26. The rates were noticeably higher in the town districts, urban areas showing an aggregate rate of 91.7 per 1,000 births and rural areas 60.9.

Hospital Amalgamation in Dublin

Speaking at the Meath Hospital at the opening of the clinical session, Dr W. Boxwell, in dealing with hospital work in Dublin, said they had all heard of the suggested amalgamation of a number of the smaller hospitals to form one great hospital of 800 or 1,000 beds. There was a time when he was dazzled by such a project, but now, when he was older, he was not so sure. Apart from the wisdom of such a scheme, from sentimental reasons, did not the small hospital, he asked, serve a very useful purpose as it now existed? The 120 beds occupied gave ample material for teaching medicine and surgery to a class of 25 or 30, the ideal number was 6, and it was impossible for one man to teach the elements of anything practical to a large class at one time. In the small hospitals the student came into direct touch with disease and with the general management of the sick, and the patient in such an institution had a larger share of the doctor's individual attention, as well as that of the student, in a great hospital there would be a class of 100, with eight or ten qualified men who would stand between the student and the practical work he was anxious and quite fit to do. He had no sympathy with the argument that by the amalgamation of four hospitals they would save the salaries of four secretaries, four matrons,

four housekeepers, etc.—whose salaries would not pay for the super secretary of the big hospital. The whole basis of the scheme was a hypothetical endowment of £500,000. It was said that by such an amalgamation they would gain centralization, that there would be greater opportunity and a wider field for the men at the head of the profession, and that accurate records would be kept. Research of a limited but very useful kind, it was argued, would become possible, but the true researcher had to be born, and money did not mean successful research. He doubted if there were a hundred men in Ireland who were setting about the investigation of the cause of cancer in any useful way. A small beginning had been made in this direction. The Government, with admirable foresight, had sent young doctors to America to learn something of the methods employed in that country with regard to bacteriology and public health. Concluding, Dr Boxwell said that so long as the face of secular education in this country was scarred by political and religious strife, and so long as they had Ministers strangling the intellectual development of a whole people, they might look in vain to the Rockefeller and every other foundation for grants in aid of scientific progress. In proposing a vote of thanks to Dr Boxwell, Mr W. S. Colles, chairman of the joint committee, said he dissented from some of Dr Boxwell's remarks on the amalgamation of hospitals. There was a great deal to be said on both sides. He ventured to suggest that the amalgamation of some of the hospitals would be very desirable if the money was forthcoming, it was an uneconomic position to have hospitals overlapping in the same district. In a hospital of 500 beds the students, he believed, would have greater opportunities of gaining experience than in hospitals of 100 beds.

Encroachments on Private Practice by Medical Officers of Health

At a meeting of the Irish Committee of the British Medical Association held at the Irish Offices in Dublin on November 14th, Dr J. Mills, chairman, presided, and Mr H. T. Warnock, F.R.C.S.I., Donegal, and Dr W. W. Murphy, Coolgreany, Inch, county Wexford, were elected chairman and vice-chairman respectively for 1928-29. Dr Walter Rabilly, Cork, requested the assistance of the Committee to prevent encroachments on private practice by whole-time medical officers of health, with regard especially to the custom of local authorities of referring to voluntary hospitals for special and institutional gratuitous treatment cases inspected by their medical officers of health. The Committee adopted the following recommendations by the Association: (1) That the function of the health authority should be confined as much as possible to the prevention of disease. (2) The work of the whole-time officer should be confined to administration, inspection, and institutional or consultative work. (3) Health visitors and nurses should be definitely responsible to a local practitioner for patients dealt with by them, including expectant mothers. (4) That in the case of private patients they should be always referred to their usual medical attendant to make arrangements for their medical treatment. The Committee discussed at length the following matters which were on the agenda of the Irish Medical Committee for its meeting, reported below, on the same date: (1) Change of area of pool for medical certification, and (2) Draft Committee of Inquiry into the working of the Local Authorities (Officers and Employees) Act, 1926. A vote of condolence was passed by the Committee with Mrs. Cassidy, on the death of her husband, Dr. Louis Cassidy.

Change of Medical Certification Pool Area

At a meeting of the Irish Medical Committee held in the Royal College of Surgeons, Dublin, on November 14th, the following members were present: J. Power (in the chair), P. J. Buttery, P. J. Clery, C. J. Corby, A. D. Courtney, P. J. Cusack, J. M. Day, J. Dalton, M. F. Delaney, W. M. Donovan, G. Fitzgerald, P. J. Hamilton, W. Hederman, E. T. King, J. J. McKenna, J. Mills, W. W. Murphy, J. Murray, J. W. O'Brien, B. O'Hanlon, J. O'Meara, H. Raverty, H. Roche-Kelly, R. J. Rowlette,

¹ H.C. 158. H.M. Stationery Office or through any bookseller. Belfast 1928. 2s. 6d. ret.

J P Shanley, D Walshe, Sir William I de Courcy Wheeler. Apologies for absence were received from Dudley Forde, J J Elliott, P McKenna, J Stuart, H T Warnock. Sir Joseph Glynn, chairman of the Irish National Health Commission, and Dr W J Maguire, medical commissioner, with the secretaries of the Commission, Mr J Honahan and Mr J Short, were present by arrangement, to discuss the proposed substitution of the county for the dispensary district as the pool area for payment for medical certification. The discussion lasted for more than two hours. Sir Joseph Glynn said that he was prepared to modify the county scheme by taking out of each county towns of a population of 2,500 and upwards, and making them certification pools in the same manner as urban areas of 10,000 and above are now constituted, and that the Commission would be also prepared to consider a diversion of a portion of the capitation fees from these urban areas to rural districts. Apart from these towns the remainder of each county was to be constituted into one pool, and the existing dispensary district pools abolished. The Medical Committee considered carefully the proposals made by Sir Joseph Glynn, and the following resolution was unanimously adopted. That the Irish Medical Committee decline to recommend the acceptance of the proposal of the Irish National Health Insurance Commission for revision of the scheme for distribution of remuneration for certification of insured persons, as the proposed change is likely to interfere with the efficiency of the certification system, and that the Minister for Local Government and Public Health be requested to receive a deputation from the Committee to discuss the question. It is understood that the Minister is prepared to receive such a deputation. A further meeting of the Medical Committee will be held at an early date to receive the decision of the Minister and to define the attitude of the profession. A discussion also took place on certain defects in the working of the Local Authorities (Officers and Employees) Act 1926, and it was agreed to refer the matter to the executive subcommittee to prepare and to submit evidence in the event of the terms of reference permitting the receipt of evidence other than from departmental or official sources.

Scotland.

The Local Government (Scotland) Bill

WITH the issue at the end of last week of the Local Government (Scotland) Bill the legislative proposals of the Government in connexion with the reform of local government and with the de-rating scheme in Great Britain are complete. In general the policy embodied in the Scottish measure follows the same lines as the proposed reforms in England and Wales, but the important differences existing in the systems in force north and south of the Border necessitate corresponding differences in the reform methods adopted, and the resulting administrative machinery after the change has been made will still leave substantial divergences in conditions in the two countries. The "discontinued" percentage grants are the same in each case, including those given for health services. The main features of the proposed reforms in Scotland are the application of de-rating the transfer of responsibility for the administration of the Poor Law, of the major health services, of lunacy and mental deficiency, of classified roads, and of certain other services to the county councils and the councils of the large burghs (that is, burghs with a population of not less than 20,000) the transfer of education to the county councils and the councils of the city-counties of Edinburgh, Glasgow, Aberdeen, and Dundee, and the abolition of the existing education authorities, which are at present bodies of the district committees in county districts, of the parish councils and of the district boards of control. The arrangements for the calculation and apportionment of the grants designed to replace the deficiency caused by the withdrawal of certain percentage grants in aid, and by de-rating will be similar to those proposed in the case of England and Wales. It is intended that the reforms should come into force in May, 1930. Consideration of the bill

by Parliament will probably be delayed until the English bill has passed through all its stages in the House of Commons. The general effect of the scheme will be to increase the importance of the councils of the counties and large burghs at the expense of the lesser authorities. In the city-counties of Glasgow, Edinburgh, Dundee, and Aberdeen the town councils will be the local authorities for all purposes, in the larger burghs the councils will control all local services save education, the county councils will be supreme in their areas except in those parts where the small burghs will preserve some degree of independence in respect of certain services. The number of Poor Law authorities, which is at present over 850, will be reduced to 52. Among the functions of the small burghs which are to be transferred to the county councils are those relating to registration of births, marriages, and deaths, to infectious, epidemic, and endemic disease, and those exercised under a variety of statutes concerning the notification of infectious disease and births, midwives and maternity homes, maternity and child welfare, venereal disease, blind persons, milk and dairies, food and drugs, and other public health subjects. Other functions may be transferred by order of the Secretary of State. It may be added that, while the county councils are to be authorized to delegate to the town councils of small burghs certain functions, it is expressly stated that the delegated functions may not include any form of medical or surgical treatment. As in the case of England and Wales, county councils in Scotland will be required to prepare for approval by the Secretary of State schemes of the administrative arrangements which they propose to make for dealing with the transferred functions, such as the Poor Law, public health, and lunacy and mental deficiency. These schemes may employ committees and local subcommittees, and where local committees or subcommittees are established they must include as members at least one-third of the total who are not members of the county council. The conditions relating to administrative schemes are less strictly defined than in the English bill. Another point of difference is the omission of any direct reference to the acceleration of the appointment of whole-time medical officers of health, it is provided, however, that when the post of a medical officer of health or a sanitary inspector in a small burgh falls vacant the corresponding official for the county shall be appointed. The result will be, in the course of time, that all medical officers of health will be in the service of either a county council or the council of a large burgh, and will therefore presumably be whole-time officers. Certain amalgamations for administrative purposes of counties and burghs are decreed in the bill, and provision is made for facilitating voluntary unions for specific purposes by local authorities. Power is taken, where a small burgh has failed to discharge its functions in respect of water supply, sewers, housing, or any other functions relating to public health, to transfer such functions to the county council for a prescribed period. While the above survey covers the main points of the bill it is by no means exhaustive, but it may be noted that the measure is in many respects simpler than the English bill, and, further, that the reformed system which is contemplated will be more highly unified than the reformed system of local government in England. The effects in the sphere of public health, and of the hospitals in particular, will be considerable. Nine-tenths of the population of Scotland will be in areas in which control, for all local government purposes except education, will be exercised by one authority, so that there is clearly scope for a great unification of health services. The hospitals and other institutions now forming part of the Poor Law service will come under the sway of the county councils and the larger municipal authorities, and the fact that the bill requires the preparation of administrative schemes relating to public health suggests that the way has been opened for a sweeping reorganization. In some cases, notably in Aberdeen and Glasgow, the Poor Law institutions—either in co-operation with the municipality or otherwise—have been developed in recent years on the lines of large general hospitals, and their association with the city and county councils will probably accelerate the movement in this direction. Only about fifty authorities will be concerned in the administration of the major health services, and the total number of local authorities in the country will not exceed 120.

Quarterly Vital Statistics

According to the report of the Registrar-General for Scotland for the quarter ended September 30th last the birth rate for that period was 19.1 per 1,000, the marriage rate 7.5, and the death rate 11.0. This birth rate is markedly below the average, and the death rate also is comparatively low. The infantile mortality rate was 69 per 1,000 registered births. The death rates from all forms of tuberculosis and from tuberculosis of the respiratory system were 87 and 60 per 100,000 respectively. The death rate from malignant disease was 137 per 100,000. The actual number of deaths from all causes registered during the quarter was 13,457. In the larger burghs, taken individually, the quarterly death rate varied from 13.1 in Dundee, 12.7 in Coatbridge, 12.6 in Greenock, and 12.3 in Perth to 8.4 in Kirkcaldy, 8.8 in Hamilton, 8.9 in Motherwell, and 9.0 in Dunfermline. In Glasgow the quarterly death rate was 11.9, in Edinburgh 11.1, and in Aberdeen 11.4. The actual deaths of children less than 1 year old numbered 1,610. In the larger burghs, taken individually, the infantile mortality rate varied from 97 in Ayr, 95 in Glasgow, 91 in Dundee, and 82 in Falkirk to 41 in Kirkcaldy, 46 in Dunfermline, 50 in Kilmarnock, and 55 in Edinburgh. The actual deaths from all forms of tuberculosis were 1,071, and the actual deaths from malignant disease 1,681. Deaths from diseases and accidents of pregnancy and childbirth numbered 147, equivalent to a death rate of 6.3 per 1,000 registered births. There were 37 deaths from cerebro-spinal meningitis, 23 from encephalitis lethargica, and 13 from acute poliomyelitis.

Hereditry and Health

A lecture delivered as one of a series promoted by Glasgow Corporation and the Burgh Insurance Committee was given by Professor Crew of Edinburgh University in Glasgow on November 14th on "Hereditry and health." Professor Crew said that hereditry had developed into a science only some twenty-eight years ago, and the time that had elapsed had hardly been sufficient to allow much application of this new science to human affairs. He considered it important that family history should be kept, for it was important both to be well born and to remain well. They could not remain healthy if the environment in which they lived was of a kind not conducive to the full self-expression of what they had inherited. He believed that for every individual exhibiting mental defect there were ten carriers of this defect, the problem of the practical application of hereditry was to identify and cure the carrier rather than to attempt to cure the defective, and he thought it was quite reasonable to ask those who were defective to remain celibate. He believed there was an indication of a general determination that as knowledge grew there should also develop a public morality fitted to use that knowledge for the betterment of humanity.

Fifty Years in Practice

Dr A. Leslie Curror was, on November 14th, entertained to dinner in Kirkcaldy by his patients and fellow townsmen in celebration of his having been fifty years in practice there. Viscount Novar presided, and during the evening Dr Curror was presented with a cleque and a silver tray bearing an inscription recording the high esteem in which he had been held during his long period of medical practice. The toast of "The Medical Profession" was proposed by the Rev. Evelyn Gall, minister of Kirkcaldy Parish Church, and acknowledged by Dr C. E. Douglas of St. Andrews.

England and Wales.

Post-graduate Course on Cancer at Leeds

A POST-GRADUATE course of four lectures on cancer, under the joint auspices of the Leeds and West Riding Medico-Chirurgical Society and the Yorkshire Council of the British Empire Cancer Campaign, will be given during the winter months at the Medical School, Leeds. There is no fee for the course, and all medical practitioners are invited to attend. The lectures, the first three of which will be illustrated by lantern slides, will in each case be given at 3.30 p.m. on a Wednesday, the first being on November 28th, when Professor A. H. Burgess will discuss cancer

of the breast. At the second lecture, on January 9th, Professor Blain Bell will deal with lead in the treatment of cancer. The remaining lectures, on February 13th and March 13th, will be given by Dr. Archibald Leitch, director of the Cancer Hospital Research Institute, London, on "The lessons of recent researches in cancer," and Mr. Cecil Rowntree, surgeon to the Cancer Hospital, London, on "Cancer and the general practitioner." Tea will be provided at each lecture, and those intending to be present are therefore requested to inform the secretary of the British Empire Cancer Campaign, 47, Park Square, Leeds, at least two days before each lecture.

St Mary's Hospitals, Manchester

The St. Mary's Hospitals, Manchester, have just issued a report, prepared by Dr. J. W. A. Hunter, on the clinical work done in their maternity department during the year 1926. Dr. Hunter points out that, owing to changes in the registrarship, it has not been found possible to compile this report in accordance with the suggestions of the Maternity Hospital Reports Committee. During the year 3,222 patients were treated, of whom 1,761 were admitted to the hospital wards. Of the latter, 17 were cases of ectopic pregnancy, 8 of tumour operated upon during pregnancy, and 230 of abortion. Thirty-six patients were admitted after delivery, mostly on account of the occurrence of puerperal complications. The mortality rate for all admissions was 2.38 per cent. Among the causes of death were heart disease complicating labour, eclampsia, obstetric shock, post-partum haemorrhage, puerperal embolism following labour, accidental haemorrhage, placenta praevia, hyperemesis gravidarum, puerperal sepsis (one case only), ruptured uterus, and abdominal pregnancy. The morbidity rate was 12.08 per cent., the standard adopted for the estimation of morbidity being that suggested by the British Medical Association—that is, "all fatal cases, and all cases in which the temperature reaches 100° F. in any two of the bi-daily readings from the end of the first to the end of the eighth day after delivery." Two hundred and six cases of contracted pelvis were treated during the year by operation. Most of these were among patients who had been kept under regular observation at the ante-natal clinic and admitted whenever treatment was considered advisable. Thirty-four patients were admitted with eclampsia, and of these seven died. The routine treatment adopted was (1) absolute starvation during the eclamptic state, (2) gastric lavage and purgation, (3) colon lavage, (4) moderate narcosis. The report is furnished with twenty-four statistical tables giving a detailed account of the clinical work done by the department during the year.

Local Government Reform in London

A special committee of the London County Council, under the chairmanship of Sir Cyril Cobb, has been examining the changes proposed in local government by the Minister of Health in connexion with the de-rating scheme in so far as they affect London, and reported to the Council on November 13th in a sense favourable to the Minister's proposals. The general nature of the scheme, which is linked up with the Government's proposals for the relief of productive industries, was explained in our issue of October 27th (p. 765). The application of the scheme to London is generally on the same principles as to the rest of England and Wales, with modifications on account of the special conditions of the metropolis. If the proposals take effect all the London Poor Law authorities will be abolished as from April, 1930, and their functions (with minor exceptions) will be transferred to the London County Council, which will become responsible for, among other things, domiciliary medical relief (as part of what has hitherto been Poor Law assistance), the provision of institutional treatment, the functions relating to lunacy and mental deficiency now performed by the guardians, and the services maintained by the Metropolitan Asylums Board.

The London County Council does not anticipate any insuperable difficulty in adapting and supplementing the present organization so as to enable the Council to undertake the new duties. With regard to the setting up of committees and of local subcommittees for the administration of the transferred functions, it is pointed out that the Minister's provisional scheme has provided that on

all such bodies persons might be co-opted who are not members of the Council, subject, however, to the maintenance of a majority of elected members. While the requirement to maintain a majority of elected members could be met on committees of the Council itself, it is felt that this would be impracticable on the local subcommittees in London, and it is therefore suggested, on behalf of the County Council, that this condition be waived in the metropolis, and that the Council be at liberty to appoint local subcommittees without a majority of its own members. Another suggestion is that in order to liberate members of the Council to serve on the new bodies dealing with the transferred functions, the principle of co-option should be extended to the existing committees (except the Finance Committee), subject to the number of co-opted members not exceeding one-third of the total membership. This suggestion is important, because many medical men and others who would be eminently useful on committees dealing with health and hospital services might be unable or unwilling to run the gauntlet of election or to take part in general administration. The Council also desires the greatest possible freedom in distributing the transferred functions, and suggests that the Minister should be enabled on application by the County Council, to make an order attributing to the metropolitan borough councils any of its powers or duties. This desire is, in fact with certain restrictions, met in the Local Government Bill, and, further, the provisions of the bill relating to the constitution of guardians committees do not apply to London. It is proposed to empower the County Council instead to provide in its administrative scheme for the appointment of local or other subcommittees of the public assistance committee, to form these committees wholly or partly of members of that committee, and to prescribe their functions. Functions under the Vaccination Acts are transferred by the bill to the City Corporation and the borough councils.

The Minister's provisional scheme proposed that the County Council should be the supervising authority for the health services in the county. The London County Council asks power to conduct periodical surveys of health services in the county and to require authorities and bodies administering health services to furnish necessary information. Surveys of this character have been made from time to time in respect of individual services, but there has been no statutory authority for them.

As the London County Council has on several occasions indicated that its policy is the abolition of Poor Law authorities and the merging of their powers in general municipal government, it was not anticipated that any opposition would be raised to the Minister's proposals, except possibly on the ground of finance. After a conference with the Minister who recognizes the special circumstances of London, which are not to be met by any general formula, it appears to the special committee that London will not be adversely affected in the matter of total grants for many years to come. After a debate in which various amendments were negatived, the recommendations of the Special Committee were agreed to by the Council.

London University Purpose of the Bloomsbury Site

In the course of a lecture to the London Society on "The physical relations of a university to a city," in the hall of the Royal Society of Arts, on November 16th, Sir William Beveridge, a former vice-chancellor of the University of London, spoke of the purchase of the Bloomsbury site by the University, and outlined the scheme for its development. The University of London, he said, had about 14,000 students, 1,100 appointed and recognized teachers, and many other teachers but these students and teachers could not be found by visiting what was called the University of London in South Kensington, they could only be found in the colleges—particularly the great colleges in the central area of London—University College, King's, The School of Economics Bedford Park, and the medical schools. Hitherto, while the bulk of the University was in the centre of London, it had no centre of its own. A year and a half ago, with the help of the Rockefeller Foundation it bought the site on the Bedford estate during the past year it had obtained powers to

close all the roads across the site so as to make an island area of ten acres. This area lay next to the British Museum, between the central colleges, near the centre of gravity of the University. The possession of the site did not mean the uprooting of any of the colleges, it was primarily for the central purposes of the University. It was hoped that it could be made for social and residential

a faculty club for teachers and administrators, and a students' union, or day house, bringing together students of many colleges. Much could be done to give to that half of the London students who did not live at home a chance of living, whether in halls of residence or approved lodgings, in an academic quarter close to the colleges. To use the site the University would need gifts on a scale not dreamed of before, these gifts would go, not to some temporary undistinguished purpose, but to benefit the lives of generations of students. The buildings erected on this site would, it was hoped, be the outcome of creative imagination in architecture. Whatever the design, two things were certain. Nothing would be built on the Bloomsbury site that was not beautiful, and nothing would be built that would not be characteristic of London and of this age.

Brompton Hospital for Consumption

Lord Derby, who is president of the Brompton Hospital for Consumption, opened, on November 14th, a new x-ray department, surgical wards, and an operating theatre. The urgent need of more convenient radiological facilities has been felt for a long time, and the present enlargement and remodelling of the old x-ray department will enable the work to be carried on with much less difficulty than hitherto. The new surgical unit consists of wards containing twenty-five beds, and, together with the operating theatre, will give great assistance to an important side of the treatment of tuberculosis. The nurses' home has been extended in order to provide for additional nurses and the establishment of a preliminary training school. One central kitchen has now been instituted and equipped with modern labour saving devices, other improvements include a new almoner's department and more electric lifts. The cost of this work of extension has been over £40,000 rather less than half of which sum has been raised already. Lord Derby commented on the excellent work for which the hospital has been responsible in past years, and emphasized the importance of such hospitals continuing to be voluntary, rather than State aided. Sir Arthur Stanley, chairman of the National Association for the Prevention of Tuberculosis said that over 4,000,000 out-patients and about 100,000 in-patients had been treated since the Brompton Hospital had started. During this time the general death rate for tuberculosis had declined by 50 per cent. For the great improvement which had taken place in the treatment of tuberculosis no small credit was due to the work of the Brompton Hospital.

Correspondence.

HOSPITAL POLICY

Sir,—As chairman of the meeting of hospital staffs in the county mentioned by Dr Norman Macfadyen in his letter in your issue of November 10th (p. 866) I should like to say at once that I do not disagree with his impressions. He seems to have put the case of the small hospitals very fairly, had the *British Medical Association* scheme been designed for these alone.

But, in starting a discussion on hospital policy, a much larger vista is opened up. The British Medical Association has pointed out—and it cannot be too much insisted upon—that the whole aspect of hospital practice has altered, particularly since the war. Whereas such institutions were formerly meant for the indigent poor, and entry thereto was regarded only as a necessity and as making the best of a bad job, they are now used by an ever-increasing number of classes, who regard them as places where the most up-to-date methods are employed, and where good treatment and comfort are alike studied. This increase in their clientele has led governing bodies to seek new

sources of income in order to keep out of debt, and it has become a fact that larger and larger numbers of patients are charged for their maintenance and nursing (In my own hospital 95 per cent pay something.) This method, however, has not sufficed to meet costs, and so contributory schemes have arisen all over the country, some on the lines suggested by the British Medical Association and some not.

The result of this revolution—as one might call it—in hospital policy is that the work of the honorary staffs has been enormously increased, on the one hand, and on the other the natural sources of their private incomes have undoubtedly been diminished. If, as Dr Macfadyen suggests, the honorary staffs were permitted to charge their patients in general wards when they could reasonably do so, the question of payment to them by the committees, in any form, would probably never arise. Dr Macfadyen, in using such terms as “free men” and “honourable independence,” seems to suggest that we should limit our present usefulness and make our action appear undignified did we take payment for hospital work.

What is there undignified in receiving payment—even if small—for work done, whether as part of a mass contribution or as a fee charged for specific service in the ward? Does not the old classic itself say “the workman is worthy of his hire”? If we were still attending the “indigent poor” then perhaps it would be undignified. But why should all these paying and contributory patients be forced to accept charity? That is what we are doing in attracting more and more patients to our hospitals by these schemes without recognizing financially the services of the staffs. Has it been suggested that it is undignified to receive five, ten, or fifteen shillings per year for friendly society attendance? Is it undignified to accept the present rate of pay under the Insurance Act? If not, then why should it be so to accept a percentage of all payments made by tariff and contract patients in hospitals?

The worker, to whom Dr Macfadyen concedes intelligence, knows perfectly well that a penny or twopenny per week individually would not pay for hospital or any other kind of treatment, but he knows also that if that sum is multiplied by ten thousand or more, it should pay for maintenance, lodging, nursing, and medical attendance, and, what is more, large numbers of contributors do believe the doctors are getting some proportion of these payments for their labour. The income from these essentially co-operative schemes is something enormous and much more than covers hospital ordinary charges.

Acting on this general knowledge of the question, it seems to me the British Medical Association suggests a scheme which appears to be dignified, fair, and business-like, and, with an eye to the future rather more than to the present conditions of the profession, the statesmanlike view is taken that the profession as a whole should be all for one and one for all.

It is the big view I would ask Dr Macfadyen, and those who think with him, to take, for without a doubt the future work, or rather future pay, of the general practitioner will become less and less. People of all stations will continue to go to hospitals in ever-increasing numbers, and, if this means increased work for the staffs, then they should receive proportional remuneration.

Some think the status of the hospital and its staff would thereby be altered, and that voluntary hospitals would cease to be such. I do not believe this for a moment. The essential feature of a voluntary hospital is voluntary management, and there is little fear, to my mind, of hospitals becoming State institutions in this country so long as there are able committees to manage them—I am, etc.,

Watford Nov 11th

G FRANCIS SMITH

SIR,—The repetition almost every second day in the last press of articles headed “Hospital treatment for all” is becoming a cause of discontent on the part of the public and I think it is only fair to the community that the medical profession should explain certain things.

First of all, hospital treatment for all classes will not be an accomplished fact for ten or twenty years. At present the accommodation for paying patients is almost negligible,

and owing to the effect of these hysterical articles in the press a surgeon spends half his time with his patient in telling him what is wrong, and half of it in explaining that he cannot take him into a private ward because there is no vacancy, and that he must go into a nursing home. There is a violent prejudice against nursing homes, because undoubtedly there have been some very bad ones. But nursing homes have the following advantages: (1) The personal interest is greater, (2) the food is better than food cooked in an institution for 200 to 600 people, (3) in all good homes, of which there are many, all the nursing staff is fully trained, whereas in hospitals part of the staff is being trained, with the patients, necessarily, as the raw material. The impression some people have received, on reading these outbursts in the lay press, is that nobody has so far ever been treated efficiently except in a hospital.

The scarcity of private wards is partly due to surgeons using them for cases which can be operated upon perfectly well in a nursing home. Private wards, as long as they are scarce, should not be used for hernias, interval appendicitis, or straightforward gastric or gall-bladder cases, but should be reserved for pyelograms, passage of opaque ureter catheter, and other procedures involving the coincident use of x-rays. The mere fact that x-rays and bacteriology help the diagnosis is not an indication for hospital treatment. Both of these forms of help can be obtained outside.

The thing that surprises me as a surgeon is that the medical profession does not realize that when hospital treatment is available for all—that is, when the country has been systematized, hospitalized, Americanized, and Germanized—it will see the end of the British general practitioner, who is the greatest in the world. If and when a case, whether the patient be rich or poor, is whipped off to hospital the moment it becomes interesting, no longer will men of ability go into that most difficult branch—general practice. The result will be that surgeons and physicians will make far more mistakes, because they will be robbed of the help of the one man who knows the patient better than any consultant can know him—I am, etc.,

Liverpool, Nov 14th.

FRANK JEANS

CEREBRAL STATES CONSEQUENT UPON HEAD INJURIES

SIR,—I have read with great interest the paper by Dr C P Symonds published in the *Journal* of November 10th (p 829), and I am in such complete accord with all that he says that I should not venture to trouble you with this letter were it not for the fact that I was unable to be present to take part in the discussion on Dr Symonds's paper when it was read at the British Medical Association Meeting at Cardiff.

The subject dealt with is of such great importance from a medico-legal standpoint that there is one aspect of it that should, I think, be emphasized.

Dr Symonds says

“My impression is that the frequency of traumatic neuroses following head injury is a good deal exaggerated and that the minor mental symptoms so often encountered are mainly due to organic damage. The argument to the contrary that such symptoms are commoner amongst workmen is to my mind of no great weight. Mental stress is an important aggravating factor in the symptoms of true concussion, and one can hardly imagine a greater mental strain than that of a lawsuit for compensation hanging over a man who has nothing to show as evidence of his disability besides his own word.”

And he adds

In this connexion I would urge the importance of teaching the legal profession that the brain may be seriously damaged without any fracture of the skull without any objective physical signs and occasionally in the absence of any history of concussion.

In endorsing these views it is, I think, necessary to call attention to the fact that the lawyers are encouraged in their belief by a section of our own profession, indeed, it is probable that their attitude is largely the outcome of views that they have heard so often repeated by certain medical men in the courts of law. It would seem to me, therefore, that we are called on to put our own house in order before we can expect the lawyers to change their view.

In considering why there should be such a divergence of opinion on this subject in the medical profession, one cannot help feeling that many doctors who adopt the attitude they do so with an inadequate knowledge of the subject, in that they have not had proper opportunities of studying these cases. If they were to study the subject with the same amount of care and thoroughness that Dr Symonds has done it would be difficult to understand how they could arrive at any opinion contrary to that which he has expressed—I am, etc.,

London W 1 Nov 12th

J S RUSSELL

WEIGHT AT BIRTH

SIR,—With reference to Dr Hubbard's query (November 10th, p 878) if 1 lb (450 grams) is an unusual weight for a child living at least seven days, I think the answer is unquestionably in the affirmative. Curiously enough in the last number of the *American Journal of Diseases of Children* an article appears on a baby of 680 grams who was living at the age of 3. The article referred to Hess's *Premature and Congenitally Diseased Infants*, in which he refers to twenty-three infants under 1,000 grams at birth as surviving. Hess himself records an infant of 690 grams living seventy-one days, and another of 740 grams living two days. It would be extremely interesting if Dr Hubbard would report the duration of life of his infant of 450 grams.

The largest infants on record appear to be one of 10,733 grams and one of 11,300 grams, reported by Dubois—I am, etc.,

Blackley Manchester Nov 16th.

J D'FWANT

SANOCRYSLIN, SUNLIGHT, AND THE SKIN

SIR,—I was much interested to read Dr Beaumont's report on the treatment of a case with sanocryslin in your issue of November 3rd (p 818). I have at present one patient—in a series of sixteen cases—who has shown a similar lilac-coloured pigmentation of the face and neck.

In this case the discoloration was particularly noticeable on the posterior aspect of the neck just above the collar, and also on his lips. As the patient developed a troublesome dermatitis all over the body, excepting the hands and face (the uncovered parts), sanocryslin was discontinued after a series of small doses (totalling 1.85 grams). The last dose of 0.35 gram was given on September 28th, and the discoloration was first noticed some three weeks later.

It never occurred to me that sunlight was the cause of this unusual manifestation, although there was certainly a good deal of sunlight here during September and early October, the patient being out in the sun for an hour or so every day.

Thiosulphate of soda was given, at first intravenously in 6-gram doses and later in large doses of 15 grams, orally, thrice daily, with local application of Lassar's paste for the extensive dermatitis. This treatment has caused the disappearance of both the discoloration of the skin and of the dermatitis, but the patient has still some small ulcers on the tongue, and, strangely enough, on the glans penis. In spite of this troublesome complication, the patient, who previously had a very long period in bed with evidence of marked toxæmia and a troublesome pyrexia, is feeling so much better that he is anxious to continue the treatment—I am, etc.,

Grampian Sanatorium Kingussie Nov 13th.

FELIX SAVA

HEART SOUNDS

SIR,—Dr Arthur Stephens (p 916) asks what authority there is for the suggestion that the auricle is capable of producing any sound. Sir Thomas Lewis has pointed out that an audible auricular sound may be an early clinical sign of the widening of the A-V interval, which is one of the earliest manifestations of heart-block. "It may not be known to everyone that auricular systole produces a distinct though muffled sound, and that while this sound is inaudible when the heart's mechanism is normal it is frequently heard when the auricular and ventricular systoles are sufficiently

separated" (*Clinical Disorders of the Heart Beat*). The precise mechanism of the production of the sound is not here specified, though it is certainly implied that it is due to muscular contraction. The same may be said of the words which Dr Stephens quotes from your *Epitome* of October 27th, and against which he directs his complaint. But the important point surely is that auricular systole is accompanied by a sound, however produced, in just the same way as is ventricular systole. Reduplication of the heart sounds may, therefore, be an early sign of heart-block.

One is naturally tempted to break a lance with Dr Stephens over his unconventional views on the production of the normal heart sounds. This temptation will be resisted, however, except with reference to one point. Speaking of the absence of heart sounds in pericardial effusion Dr Stephens says, "were the sounds produced by the muscles or valves of the heart they would be heard all the more plainly, because fluid is such an excellent conductor of sounds." It is true that liquid (not fluid) is a good conductor of sound. It is also true that the normal pulmonary sounds become inaudible, in the vast majority of cases, when the pleural cavity is filled with liquid (a good conductor) or with gas (a fluid and a bad conductor). We do not, therefore, argue that the pleural fluid is responsible for the normal breath sounds. The physical factors involved in the transmission of audible vibrations from within the thorax, via the stethoscope, to the ear of the auscultator seem still to be very imperfectly understood. There are two main causes for the loss of intensity of a sound in its passage from heart or lung to the surface: they are diffusion and reflection. A sound will lose half its intensity, by diffusion, in spreading from a sphere of given size to one of double its dimensions. In addition, reflection of sound waves occurs at the planes which separate media of different density. Assuming that we have to deal with a pericardial effusion which has doubled the cubic contents of the pericardium the effect of diffusion will be to halve the sound. The added effect of the reflection of the sound waves as they enter and leave the liquid medium is quite sufficient to account for impaired or absent heart sounds.

A very simple experiment will convince Dr Stephens that liquid, although a good conductor of sound, may be a potent obliterater of sound. If he will bury his head in the bath he will find it difficult to hear the gong. According to his own argument it should "be heard all the more plainly, because fluid [that is, liquid] is such an excellent conductor of sounds"—I am, etc.,

London W 1 Nov 17th

MAURICE E SHAW

THE SO CALLED TITANIUM RAYS

SIR,—During the last few weeks I have had a number of insistent inquiries from doctors and patients as to the meaning, nature, and value of "titanium rays" in treatment. One of these doctors brought me a pamphlet (which I enclose) entitled "Notes on titanium rays."

The impression of anyone, without some technical electrical knowledge, on reading this pamphlet must be that here is a new form of treatment entirely different from any of the well-known forms of ultra-violet light treatment. The writer's opening paragraph states:

Titanium rays are obtained from electrodes containing from 1 per cent to 5 per cent of the rare metal titanium and 95 per cent or more of wolfram.

And in another paragraph he goes on to say:

"For many years I made a special study of tungsten rays and used them exclusively. In the latter part of 1924 I began to observe the effect of titanium rays and the results led me to adopt them."

May I rewrite these paragraphs as they should be written in order to be physically accurate and to impart information on the subject to those with little or no technical knowledge?

Titanium can be incorporated in quantities of 1 to 5 per cent with wolfram which is a tungstate of iron and manganese to make electrodes for the generation of ultra violet light. For many years I made a special study of tungsten electrodes and used them exclusively for generating my supply of ultra violet light. In the latter part of 1924 I began to observe the clinical effect of incorporating small quantities of titanium in electrodes of wolfram and the results led me to adopt them.

These electrodes will, therefore, give a combined spectrum of the metals titanium, iron, manganese, and tungsten.

So written it would be clear: (a) That treatment with these electrodes was essentially an ultra-violet light treatment. (b) That the arc from these electrodes only differed from the tungsten or mercury vapour or carbon arc in the position and intensity of its absorption bands. (c) That clinical experiences with such an arc showed improvements in results in comparison with the results obtained from using tungsten only. It would then be open for any critic to point out, as Dr B D H Wotters did in the *Lancet* of August 11th, 1928, that the spectrum of titanium and tungsten are extraordinarily similar, and that improved clinical results from the mixture of the titanium and tungsten were difficult to credit.

It would be equally open to the writer to reply that wolfram is not pure tungsten, though it is the chief source of supply of tungsten, and, from the controversy, interesting clinical facts might emerge and stimulate the Medical Research Council to investigate the claims and issue an authoritative statement. As set out, however, the statements must necessarily cause confusion, and thus, at a time when the British Medical Association is endeavouring to counteract extravagant and unjustifiable claims in relation to ultra-violet light, is, to say the least of it, unfortunate.

May I conclude by urging those who are utilizing electro-physical methods of treatment in their practices to employ correctly the generally accepted terms of physics when they put their views into print?—I am, etc.,

EARLY RECOGNITION OF CANCER OF THE STOMACH

SIR,—In the very helpful article on the early recognition and treatment of cancer of the stomach, published on November 10th (p. 838), the author writes: "A disadvantage of the usual benzidine test is that it is over sensitive for clinical use, giving a positive reaction with traces of blood which are too small to be significant."

This criticism of the test was shown to be fallacious by J G Spence in the *Newcastle Medical Journal* of January, 1927.

Since reading this article I have found it possible to get negative results repeatedly without dieting the patients. Having in my own case obtained a negative result, I deliberately consumed a large quantity of underdone meat, but the test still remained negative. The only precaution I have found necessary is a most rigid cleansing of the tube or porcelain dish used in emulsifying the faeces. Obviously any lack of this precaution in the other tube containing the benzidine-gliocil acetic acid-hydrogen peroxide mixture will declare itself. If the result is negative I always confirm the activity of my reagents by adding a few drops of a solution composed of one drop of blood from my finger in a three-ounce dispensing measure of water. The reagents are cheap and keep well if the hydrogen peroxide be kept in the earthenware stoppered bottles it is now usually supplied in.

I quote the above article and my own experience in the hope that they may be of service in commending this simple and helpful test to others.—I am, etc.,

London S W 11, Nov 14th.

W BAL PEACOCK, MD

THE DIAGNOSIS OF GASTRITIS

SIR.—Certain of Dr Hurst's statements on November 3rd (p. 779) require, I think, some comment. He says the fractional test meal affords the only means of recognizing gastritis, surely he does not mean to suggest that gastroscopy in the hands of a competent and experienced man is not also a means of diagnosing this condition. Among the newer methods of diagnosing gastritis is one which is employed in the Charité in Berlin—a radiological method. The patient receives a rather small quantity of barium, is placed before the screen, and by means of pressure applied to the abdomen in the stomach region by the radiologist the barium can be made to occupy the spaces

between the mucous membrane folds. An impression may thus be gained as to the presence of abnormal thickening or conformation of the folds, by the experienced eye slight variations from the normal may be detected. If desired a picture may be taken after the screening (with this small quantity of barium in the stomach), and it is often very impressive to see abnormalities of the mucous membrane shown up in this way. This change in the mucous membrane is surely sufficient ground on which to base a diagnosis of gastritis.

Is excess of mucus in the test meal fractions necessarily a sign of gastritis? That gastritis is the commonest cause of excess of mucus no one will question, but many physicians recognize another condition—the so-called gastro-myositis—in which there is an increased secretion of mucus without any pathological condition of the stomach wall being present. They regard it as to an extent analogous with true mucous colitis and of nervous origin in the purest meaning of the term.

Then Dr Hurst asserts "the essential exciting cause of gastric and duodenal ulcer is infection." Surely this is too dogmatic a statement. As regards causation, there exist at present numerous theories, but they are as yet only theories. Those people who deny the infection factor have much on their side, and, after all, they may be right. Two workers who do not subscribe to the infection theory are Aschoff and v. Bergmann, I may add, incidentally, that these two are by no means in agreement as to the causation, but they unite in regarding infection as being a rare cause of ulceration, surely the opinions of two such men are worthy of consideration. The causal factor is still unknown, and so long as we have only theories and no definite proofs as to the leading part played by any one factor, no one is justified in saying "that or that is the essential exciting cause."

It might interest Dr Hurst to know that Kalk of Berlin has shown that, after giving test meals of milk alone, he has found acid values exceeding those found after the usual test meals (for example, 5 per cent alcohol, etc.), he prefers to give as little milk as is necessary to ulcer patients because of its exciting action as regards acid production. His finding clashes with those of Freezer, Gibson, and Matthews, who believe milk has a neutralizing effect on the hydrochloric acid produced in the stomach. Both opinions cannot be correct, and it would be very interesting to find out absolutely definitely the action of milk, considering that it is the basis on which most of the existing ulcer treatment schemes are built.—I am, etc.,

Berlin Nov 6th

P J MOLLOY, MB

DEFINITION OF DRUNKENNESS

SIR.—Once more I have just returned (10.45 p.m.) from the local police station, after seeing a man suspected of being drunk in charge of a motor car. Primed with the letters of advice in the *British Medical Journal* on my recent case of a similar kind, I went prepared to say "Drunk" without any qualifications.

The man had been drinking, but he passed every test that I could put to him, yet I knew he was not fit to drive a motor car.

Acting on the advice given me in one at least of the letters, was I to perjure myself and say "Drunk" without comment, was I (taking the advice that my duty was "to be guided by the law") to say the man was "Not drunk as at present defined," or should I say once more "Not drunk in the ordinary sense of the words [however loose the description may be] but unfit to be in charge of a car"?

My experiences of the recent sessions, my curtain lecture by the chairman, my cross-examination by the grand jury, have left their mark.

The accused stepped out a free man. Fortified by coffee kindly supplied by a good-hearted sergeant, delayed by the mending of a puncture which (not unintentionally) was not unduly hurried by the mechanic with no intoxicant in his pocket and public-houses closed for the night, I have every hope he arrived home safely without damage to himself or, what is perhaps more important, damage to others.

Still, my conscience asks me: Have I done right?—I am, etc.,

Crawley Nov 13th.

SIDNEY MATTHEWS, JP

SIR,—Most of the definitions of drunkenness hitherto suggested, including that of the British Medical Association's Committee and those of the two judges referred to by Dr H J Fardou in his letter on November 17th (p 916), appear to have been specially drafted to apply to the offence of "being drunk in charge of a motor vehicle." In many of those circumstances in which drunkenness is a statutory offence no element of danger, no failure to attain safety, is involved. Any satisfactory definition of drunkenness must be valid in *all* the circumstances detailed in the statutes in which the word "drunkenness" or equivalent expressions are used.

In decisions given by benches of magistrates or by juries it must be remembered that no standard of intelligence beyond ordinary sanity, and no knowledge beyond that gained by ordinary experience, are presupposed. It must also be remembered that the law evidently deems drunkenness to be within the ordinary objective experience of any man and therefore not requiring definition.

Observation and induction from a study of the statutes concerned, I think, justify the statement that to the ordinary individual drunkenness in law is a demeanour directly due to the voluntary consumption of alcohol, which is calculated to interfere with the comfort, convenience, and safety of the public. But it is for the court to decide whether this condition obtained at the time of the alleged offence. It is the duty of the medical witness to declare whether the individual he examined was drunk or not, and in my opinion he should not ask anyone in court what is meant by drunkenness, if he feels unable to define drunkenness he should say so, and content himself with the detailed statement of his examination. But the chief value of medical evidence of drunkenness is the elimination of the possibility that some pathological condition simulating drunkenness existed.

I will not occupy your space with the reasoning upon which my definition of drunkenness from a medical view is based, but merely state it. Drunkenness is any alteration for the worse in an individual's normal behaviour, judgement, and skill, or any one of them, due to the consumption of alcohol. If the medical witness has had no previous acquaintance with the individual or has had no opportunity of a subsequent examination when no alcohol has been consumed, he should make it clear that his standard of "normal" is one based upon the reactions of an average healthy person to ordinary environments.

It will be found in practice that if the opinion and evidence of the medical and other witnesses coincide with the conception of drunkenness held by the court—namely, that it is a demeanour calculated to interfere with the comfort, convenience, or safety, one or more of them, of the public—a conviction will follow.—I am, etc.,

Thurstone St Sheffield Nov 18th

GORDON WILSON

"HYPERVITAMINOSIS"

SIR—Your issue of November 10th contains an interesting leading article (p 856) in which reference is made to this subject. I am certainly in agreement with the general conclusion which you draw from the results obtained by Dr Moore and myself, and by other investigators, that there need be little danger in clinical practice of poisoning from excessive dosage with irradiated ergosterol. At the same time it would be an exaggeration to exclude its possibility. In quoting our reference to the work of Hess and Lewis you state that these authors had observed *no toxic effects* in infants. May I point out that what we actually said¹ was that Hess and Lewis had observed *only two instances of clinical disturbance*, due to hypercalcaemia.

The following conclusions can, I think, be fairly drawn from the data available:

1 Clinical experience proves irradiated ergosterol to be an absolute specific for rickets and preferable to cod liver oil for this purpose.

2 The dosage of 2.5 to 5.0 mg. of irradiated ergosterol which has been widely advocated for the treatment of rickets in infants is however unnecessarily large being roughly equivalent to some seventy teaspoonfuls of good cod liver oil.

3 In Hess and Lewis's extended experience of dosage at this high level there did occur several instances of hyper-

vitaminosis—namely, three cases of high blood phosphorus (without apparent ill effects) and several cases of "ebullation" (excessive calcification of bone) and of hypercalcaemia, only two of the latter manifesting untoward chemical disturbances, which cleared up when the excessive irradiated ergosterol was withdrawn.

4 An adequate dose appears to be 1 mg. for an average case of rickets, and 0.5 mg. prophylactically for an infant (Hess and Lewis).

5 Further tests are needed in order that the dosage may be more precisely standardized.

6 Since various specimens of irradiated ergosterol may vary in antirachitic activity, it is desirable that they should be subjected to physiological assay before being issued.

7 It is conceivable that different specimens, irradiated by different methods, may contain varying amounts of any toxic by-product; the optimum manufacturing procedure needs to be worked out.

—I am, etc.,

LESLIE J. HARRIS, D.Sc., Ph.D.

Nutritional Laboratory (Medical Research Council)
Cambridge Nov 12th

RICKETS AND OSTEOMALACIA

SIR,—I am anxious to obtain information—probably from India or China—as to any difference between rickets and osteomalacia.

We know that in both these conditions Ca and P leave the body in the faeces and urine, and in both softening, and later deformity, of the bones occur, in rickets this is specially marked at the epiphyses, in osteomalacia tenderness and softening develop in the shafts or centres of the bones (ribs, pelvis).

The difference seems as if it were due to the fact that in one case there is insufficient deposition of Ca and P (as shown by delayed eruption of teeth and softening at the costochondral junctions), in the other there is loss of Ca and P already deposited in the adult skeleton, showing itself in bending of shafts of long bones, deformity of ribs, pelvis, and decay of teeth. Perhaps in rickets sufficient Ca and P do not get to the growing bone, and in osteomalacia the same defect in metabolism removes Ca and P already deposited.—I am, etc.,

London W 2, Nov 12th.

KATHLEEN VAUGHAN

TRAUMATIC RUPTURE OF SPLEEN

SIR,—In connexion with the recent correspondence in the *Journal* concerning traumatic rupture of the spleen, a further case of delayed haemorrhage, which has just been discharged from this hospital, may be of interest.

A girl aged 22 was thrown violently from the pillow of a motor cycle on October 4th her mother who was in the vehicle being killed outright. The girl had abrasions of the face and knee but no signs or symptoms of abdominal injury. A week afterwards she was allowed to get up for an hour in the evening and made no complaint of pain or faintness. A few hours later, however, she had violent abdominal pain and collapsed; the abdomen was rigid and slightly distended, and her pulse was imperceptible. A diagnosis of intra-abdominal haemorrhage was made, and as her pulse improved slightly in quality but remained very rapid she was taken to the theatre.

A left paramedian incision was made about the level of the umbilicus; the peritoneal cavity was found to be full of blood. Both tubes were normal but there was a tear in the anterior border of the spleen about two inches long. The spleen itself was surrounded by soft adhesions and blood clot. Although the incision was extended by means of a transverse division of the rectus muscle it was impossible to free the injured organ. As the patient was almost pulseless the tear was firmly packed with gauze and the incision was sewn up rapidly after leaving two pints of saline solution in the peritoneal cavity.

The pack was gradually withdrawn during the following fortnight and she was discharged without further symptoms or recurrence of the bleeding.

—I am, etc.,

JOHN F. HACKWOOD, F.R.C.S. Eng. and L.D.

November 11th Resident Medical Officer Farnborough Hospital

VALERIAN

SIR,—Dr Manson's paper on valerian (November 10th, p 842) should revive an interest in this much maligned remedy. I find it difficult, however, to follow his theory of the psychical action of this drug. Surely the experiments of Mr Kenneth dealt with conditioned reflexes; the olfactory stimulus was the key that unlocked the first of

¹ See *Lancet* October 27th p 893 and November 3rd p 856.

the many doors to the particular complex. But unless one assigns to valerian the virtues of a master key, how can it be expected to open locks of many different patterns?

Dr Manson's indications for the use of this drug are valuable, it is interesting to note that they confirm the schema worked out by Kent in his lectures on materia medica. Valerian seems to act on every level of the human nervous system. Gordon has reported a case in the *New York Journal* (1924) of an addict who developed a cerebellar syndrome. Langdon Brown has called attention to the value of this remedy in diabetes insipidus. Its value in flatulency and meteorism is well recognized, both these conditions are relieved by the injection of posterior pituitary substance. The relation seems of some significance, but, as Dr Manson notes, further research is necessary.—I am, etc.,

Clifton Nov 13th

FRANK BODMAN, M B, M R C S

Obituary

C P THOMSON, D S O, M D,

Major R A M C (ret),

President of the Sanitary, Maritime and Quarantine Board of Egypt

WE regret to announce the death, on November 14th, at Alexandria, of Major Charles Pinkerton Thomson, D S O, R A M C (ret), who had been president of the Egyptian Quarantine Board since 1925. He studied medicine at the University of Glasgow, graduating M B, Ch B in 1900, and proceeding M D in 1904. Before entering the Royal Army Medical Corps he had been house physician to the Western Infirmary, Glasgow, and resident medical officer to the Guest Hospital, Dudley. For the appreciation that follows of his work in Egypt we are indebted to Sir George Buchanan.

The sudden death of Major C P Thomson, reported from Alexandria at the end of last week, must have come as a shock to many of his former colleagues in the Egyptian public health service, who remember the sterling value of the work he carried out in the branch of that service which was concerned with the control of epidemics, and directed during the war and in the years immediately following it. Owing to ill health, as well as to administrative changes in Egypt, Major Thomson retired from his medical service and from the army in 1923, but three years later he responded to the demand that he should accept an important executive office for which, in the eyes alike of the Egyptian and British Governments, he was particularly fitted. This was the presidency of the Sanitary, Maritime, and Quarantine Board of Egypt, an Egyptian institution of international composition, whose duties and position had been established by the successive International Sanitary Conventions, and which had the double duty of protecting Europe and the Levant from the importation of cholera and other epidemic diseases from the East, and of providing a sanitary service for the ports of Egypt itself. Major Thomson had two distinguished predecessors in this office, first the late Sir Maro Armand Ruffet, under whom the main lines of the sanitary defences on the Suez Canal had been laid down, and the great quarantine establishment at El Tor, for the north-bound pilgrims returning from Mecca, had been established, and next Dr Alexander Granville, C M G, who with infinite tact and diplomacy had enabled the Board to maintain itself during the war and to re-establish itself effectively during the uncertain political years which followed. Major Thomson's appointment was made at a time when it was evident that the Board needed new life and required for its justification to come into the front rank with the other international bodies which are concerned with the prevention of epidemic disease, and to be modernized so as to secure the confidence of shipping interests as well as of sanitarians. In the three years which have now so unfortunately and abruptly terminated Major Thomson fully justified the trust reposed in him. He took up actively, even aggressively, each section of the work of the Board, gained the confidence and support of its members and of the authorities in Egypt, and effected an invaluable reorganization of the numerous different services and

institutions concerned, securing in the process a reduction of expenditure and a diminution of the charges on shipping. The position of the Board was already strong enough, in 1926, to enable the International Sanitary Conference at Paris not only to confirm its duties under the previous conventions, but to place on it several important new duties, such as the sanitary regulation of coasting traffic in the Red Sea, and the collection and dissemination of information on all matters affecting the sanitary control of the Mecca pilgrimage. An article of the International Sanitary Convention, 1926, also enabled the International Health Office in Paris, after consultation with Major Thomson, to arrange with the Sanitary, Maritime, and Quarantine Board of Egypt to set up in Alexandria a "regional bureau" for intelligence regarding infectious disease which would act for the Levant and Near East in the same way as the League of Nations' regional bureau at Singapore acts for the Far East, and the Pan-American Sanitary Bureau at Washington for the Americas. This new intelligence service of the Board at Alexandria, under the direction of Major J Gilmonr, M D, has proved a notable success, and has already done much to simplify the complicated problem of avoiding unnecessary and vexatious methods of quarantine, and to improve the medical control over the annual pilgrimage to the holy places of Arabia. All of those who were privileged, only last month at Paris, to hear Major Thomson's exposition of the administrative system which is in operation or in course of development for these purposes, must have recognized in him that stamp of knowledgeable, honest, and forceful personal endeavour which means so much, and will the more appreciate the loss to international public health progress which his sudden death has created.

Medical-Legal

DOCTORS AND AGENCY LAW

THE decision of His Honour Judge Cunn at Eastbourne County Court on November 13th, that a medical man was liable for the hire of a motor car to convey a patient from Eastbourne to Bournemouth because he did not disclose to the car owners that he was acting as the agent of the patient in ordering the car, serves to illustrate the passage relating to the undisclosed principal in *Anson on Contract*, fourteenth edition, at page 418.

If the agent acts on behalf of a principal whose existence he does not at the time disclose the other contracting party is entitled to elect whether he will treat principal or agent as the party with whom he dealt.

The facts of the case were that the plaintiffs, Messrs Maley Bros motor engineers, on August 11th, 1923, received a telephone message. Dr Churcher speaking. Send me a car at once to 8, Mead Street, to take a patient to Bournemouth, and later a further telephone message. "Is that car coming that Dr Churcher ordered or not?" The order was duly executed. It appeared from Dr Churcher's evidence that he had never seen the patient before that date, and therefore, did not know he was impecunious, and, further, that although he in fact obtained the patient's consent to the ordering of the car to convey him to his parents' home he (Dr Churcher) did not inform the plaintiffs that he was merely acting as agent for the patient.

Mr H C Dickens, counsel for the defendant, urged that a doctor's character as agent for a patient was so notorious as to amount to a custom which excluded any personal liability.

Judge Cunn, dealing with this point in his reserved judgment, said it might be that in some matters of ordinary routine a doctor was notoriously the agent of his patient, but the contract under consideration was for a journey of over 120 miles, including the return journey. He could not hold that there was any usage or custom entitling a doctor to enter into a contract on behalf of a patient such as that upon which the plaintiffs sued. Such a usage or custom—if it existed—might have disastrous results, as it would tend to discourage or, at any rate, pending inquiries delay, the supply of articles or the rendering of services ordered by a doctor in an emergency where the saving of life might depend on prompt measures being taken. The plaintiffs throughout looked to Dr Churcher for payment, and were entitled to judgment with costs.

Mr Dickens having intimated that it was desired to make this a test case, the judge gave leave to appeal, conditionally upon the defence undertaking to pay the plaintiffs' costs of the appeal.

The defence was undertaken by the Medical Defence Union, the solicitors being Messrs Hempsons.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

ANNUAL MEETING OF FELLOWS AND MEMBERS

THE annual meeting of Fellows and Members of the Royal College of Surgeons of England was held at the College on November 15th. About forty were present.

The **PRESIDENT** (Sir Berkeley Moynihan) placed before the meeting the annual report of the Council. He said that the report included the result of the poll of Fellows taken last year on the question whether it is desirable that Members of the College should have direct representation on the Council. The number of Fellows who voted No was 846 and the number who voted Yes 234. He had compared the figures with those of a similar referendum taken in 1897. The proportion of Fellows replying was almost exactly the same on both occasions but the proportion of opponents to the proposal had decidedly increased. Proceeding to other matters in the report, he referred to the scheme for holding in Canada a primary examination in anatomy and physiology for the Fellowship. This had been arranged with the Canadian Medical Association, the examination to be held in Toronto in July or August of next year. Two examiners in anatomy and two in physiology were to be sent by the College from England and professors of anatomy and of physiology, or such other persons as might be nominated by the Canadian Medical Association would be appointed by the College to act as assessors to the examiners. He added that arrangements of a similar kind were in the making with the recently formed College of Surgeons of Australasia, were it not for the length of time the Australasian post required this matter would have been brought to completion before now. In connexion with the recent International Conference on Cancer Dr Regaud of Paris and Sir George Newman had been admitted Honorary Fellows of the College. Mr C Thurstan Holland of Liverpool and Sir Matthew Pell Director General of the Army Medical Service, had been elected Fellows under the rule relating to admission to the Fellowship without examination of Members of twenty years standing. The President also referred to the various awards and prizes including the institution of the Hallett prize, and to bequests to the College a sum of £5,000 by the will of Mr W Thelwall Thomas whose death was greatly regretted and a sum of nearly £30,000 left by Sir George S Mackenzie in 1910 to come to the College on the death of a survivor which had recently taken place.

Dr **REMOND ROCHE** suggested that the demonstrations given in the College should have a wider clinical interest for Members. He also pointed out with reference to the poll of Fellows that a larger number had refrained from voting (770) than the majority registered against the claims of the Members (512).

Dr **M FINCHAM** carried this last point further when he claimed that the number of non-voting Fellows should be added to those voting in favour of the Members. Their abstinence from voting could be construed as a recognition of the justice of the Members' claims. He criticized the scheme for holding the primary examination for the Fellowship in the Dominions, urging that if the Fellowship was worth having it was worth coming over to this country to take.

Dr **DAVID ROXBURGH** urged that there was no guarantee that the candidates examined in Canada or Australia would be of the same standard as the men who now passed through the College. He thought the standard of examination was set not by the examiners but by the candidates. If any Members in this country wanted to get the Fellowship on easy terms their best procedure would be to go over to Canada and take the examination there.

Dr **BROWN CASTREW** as a Member of the College said that the Society of Members was making altogether too large assumptions. One of their spokesmen had just assumed that all the non-voting Fellows were on the side of the Members and in a circular which he had received from the Society of Members it was stated. Since we are assured that you are in favour of this necessary reform. He himself was very far from being in favour of it and he was going to vote in the opposite direction.

The **PRESIDENT** replying said that he would call Sir Arthur Keith's attention to the suggestion by Dr Redmond Roche regarding demonstrations at the College. With regard to the poll of Fellows in 1897 the numbers who voted No and Yes respectively were 485 and 201. The corresponding numbers on the recent occasion were 846 and 234. If Fellows did not vote at all their sympathies could not be claimed by either side. With regard to the primary Fellowship examination in Canada the Council had taken over a year to consider this question. Meetings took place with persons from Canada, and there had been a full correspondence with the authorities. The Council felt that it was an injustice to a man who happened to live in Canada and desired to become a Fellow of the College that he should be compelled to undergo unnecessary hardships in the matter of doubt-travelling. Sir Berkeley Moynihan said that he like many others who joined the profession had been poor as a boy had no

lived in Canada he could never have taken the examination, because he could not have afforded to come over, even once. There was not the slightest intention by the Council to weaken the primary Fellowship examination. The standard would be fully maintained by having visiting examiners who had acted in the same capacity in this country. They would go out to Canada and conduct an examination there exactly as it was conducted here. The College intended to have its own examiners and none would be more inflexible about the maintenance of the standard than the College Council. Nor was there the smallest intention on the part of the Council to have the final Fellowship examination taken outside this country. A question had been raised with regard to the removal of a Member whose name had been erased from the *Medical Register* for adultery with a patient. He said that in such cases the Member concerned was before removal given an opportunity if he so desired of being seen and heard in his own behalf by the College authorities. In conclusion he said that he was glad to hear some expressions from Members of their deep affection for the College. The affection was reciprocated by the Council with whom some Members were in conflict on a very minor point. (Oh!)

Dr **ERNEST E WARE** President of the Society of Members then moved the usual resolution affirming the desirability of admitting Members to direct representation upon the Council and urging that in consideration of the importance of the health of the nation and of the fact that some 18,000 Members were in daily contact with the sick it was most desirable for the benefit of the public as well as of the College that Members fulfilling such an important function should have some share in the deliberations of the College to which they belonged. He said that the first part of this resolution had been carried on thirty-nine previous occasions. This was a long time for pressure to be exercised and the result had been to produce atrophy of the centres of logic and justice in the brains of the majority of the Council. With regard to the poll of Fellows he maintained that the circular sent out from the College was a biased document suggesting as it did with great subtlety that if Members got representation on the Council of the College the privileges of the Fellows would be curtailed. It was constantly said that the small attendances at the annual meeting—not much above the number necessary for a quorum—was an evidence that there was no genuine interest in this claim. But London unlike the provinces was notorious for smallness of attendance at medical meetings of all sorts. He added that the Strangeways collection which had been offered to the College by the trustees was the work of a Member not a Fellow and that many of those whose names were given in the report as having made additions to the museum during the year were Members and not Fellows. If the College as the President had said on the last occasion existed for the benefit of the public who was so well aware of the needs of the public as the general practitioner? In the inquiries which the Ministry of Health was now conducting especially into the onset of various diseases it would naturally turn to the College Council but only if that Council included general practitioners could the most valuable help be given from this point of view.

The resolution was seconded by Lieut Colonel L E LAYTON OWEN and supported by Dr F W COLLINGWOOD, Dr R GILBURN, Dr F G LLOYD and Dr HOWARD STRATFORD. The last named touched on the importance of forthcoming legislation concerning Poor Law hospitals and other health services. What would be the position of the College on whose executive the general practitioner had no place when the Government of the day asked advice and assistance on measures which threatened to extinguish general practice altogether?

The **PRESIDENT** replied that general practitioners were fully represented by the Fellows of the College. At least two-thirds of the Fellows—he put it at the minimum—were general practitioners. (Not on the Council Sir.) They voted for the Council. The members of the Council held themselves—he certainly held himself—to be the representatives of the general practitioners among the Fellows. It was quite true that this was the fortieth successive year in which this resolution had been moved and carried. Either the proposition was undesirable in itself or it was presented inadequately or unacceptably. He would like to take up the pathological metaphor used by Dr Ware. The only pressure which these who brought forward the resolution exercised upon the Council was a momentary spasm of pressure for something over an hour once a year. For the rest of the year they were slumbering in the matter. The proposition had its own strong supporters within the Council and the Council had heard all the arguments that the Members put forward at the annual meetings and others that they had not yet thought of. The decision of the Council had been so far against it. If the resolution was carried on this occasion he would see that it was again presented. He took strong exception to the statement that the circular sent out to the Fellows on the occasion of the poll was biased. It was prepared most carefully and contained not one word of partisanship. It was a straightforward statement and the facts it set out could not be denied. The case of the Members would not be advanced by wilful and repeated misstatements.

The resolution was carried by 20 votes against 2.

UNIVERSITY OF LONDON

PROFESSOR G. E. GASK, D.S.O., F.R.C.S., of St. Bartholomew's Hospital Medical College, has been elected Dean of the Faculty of Medicine.

A course of five lectures on the role of bacteria in *Natura* will be given by Dr. I. W. Twort, superintendent of the Brown Institution in the theatre of the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C. on December 3rd, 5th, 7th, 10th, and 12th at 4 p.m. Admission is free, without ticket.

UNIVERSITY OF OXFORD

Rudcliffe Travelling Fellowship

AN examination for a Fellowship of the annual value of £300, and tenable for two years will be held at the University Museum commencing on February 12th 1929, at 10 a.m. Candidates must have passed all the examinations required by the University for the B.A. and B.M. degrees, and must not have exceeded four years from the time of passing the last examination required for the degree of B.M. The successful candidate must, before election, declare that he intends to devote himself during the period of his tenure of the Fellowship to the study of medical science and to travel abroad with a view to that study. The Fellowship will be vacated *ipso facto* if more than nine months is spent within the United Kingdom. The Regius Professor of Medicine and the Examiners present a yearly report on the work done by each Fellow to the electors who may, if they think the report unsatisfactory, declare the Fellowship forfeited. The examination will occupy four days. Papers will be set in physiology, pathology, and preventive medicine and a subject will be proposed for an essay; there will also be a practical examination in pathology. Any candidate desiring to offer, in addition a special branch of either medicine or surgery must notify the Regius Professor by January 30th. Intending candidates should send their names, addresses, qualifications etc. to the Regius Professor of Medicine, University Museum, Oxford by January 30th.

UNIVERSITY OF SHEFFIELD

THE Council has appointed Dr. Alan Ljun to the post of assistant bacteriologist.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons next week will take the second reading of the Local Government Bill. This week it read the Unemployment Insurance Bill a third time and the Imperial Telegraphs Bill a second time, besides considering estimates for the Colonial Office and for other services.

The Parliamentary Medical Committee met at the House of Commons on November 14th. Dr. Fremantle was re-elected chairman and Dr. Drummond Shiels secretary of the Committee. The Committee agreed to meet during the second reading debate on the Local Government Bill to decide its attitude towards the bill and to discuss possible amendments to it.

Mr. Neville Chamberlain promised to speak on the Local Government Bill at a special meeting of the Health and Housing Committee of Conservative members of Parliament on November 21st, Dr. Fremantle presiding.

National Health Insurance.

Expenditure on Sickness Benefit.—Replying on November 15th to Mr. Rhys Davies Mr. CHAMBERLAIN announced that an examination of the expenditure of certain large approved societies in the first half of 1928 indicated broadly, after allowing approximately for the cessation of benefit to persons over 65, that the expenditure on sickness benefit in this period was rather less than in the corresponding period of the preceding year in the case of both men and women. A severe influenza epidemic materially affected the claims in the early months of 1927. The cost of disablement benefit was, however, somewhat heavier in 1928 in respect of each sex. In 1927 the expenditure on sickness benefit under the National Health Insurance Act was, for men 115 per cent of the expenditure in 1925, and for women 112 per cent. For disablement benefit the ratios were, men 124 per cent and women 128 per cent, for maternity benefit the ratios were, men 90 per cent and women 103 per cent.

Prescription of Liver Extract.—Mr. CHAMBERLAIN answering Mr. Ammon on November 15th, said that the decision whether liver extract or other preparations could be regarded as drugs or medicines within the meaning of the National Health Insurance Acts rested primarily with Insurance Committees. In answer to inquiries made by such committees he had indicated that he had no objection to suggest that liver extract could properly be regarded as excluded from the scope of medical benefit in any cases in which it was requisite for the patient's treatment. He did not think that he had any power to issue a regulation on the subject.

Bills

Sunday Closing of Barber's Shops.—On November 20th Mr. JAMES STEWART asked leave to introduce a bill to provide for the compulsory closing of hairdressers' and barbers' shops on Sundays. He explained that the bill which he has introduced on several previous occasions, dealt with what was a dangerous trade. The conditions under which the people in the barbers' shops worked were injurious to their health. Many of the shops were unhealthy and if there was a proper standard of inspection would not be allowed to carry on. The workers in this trade worked longer hours than did the average shopkeeper, the average being from 60 to 70 hours a week. In 1914 one out of every five of the persons engaged in the trade died of consumption, and to-day if members of Parliament went to a barber's shop they must remember that one out of five of the men who looked after them was a source of infection. Leave was granted to bring in the bill, which was read the first time.

Sir ROBERT GOWER presented on November 14th, a Protection of Dogs Bill, to prohibit the vivisection of dogs. The bill was supported by Colonel Moore, Mr. Bromley, Mr. Thurtle, Captain A. Evans, Mr. Sexton, Mr. Radford and Commander Kenworthy.

On the same day Sir ROBERT GOWER presented a Housing Bill "to amend provisions in Part II of the Housing Act 1925, relating to improvement and reconstruction schemes. This bill is concerned with the question of compensation for property demolished under slum clearance schemes.

Encephalitis Lethargica and Vaccination.—Mr. CHAMBERLAIN in a reply to Mr. Bryant on November 15th said that 1,394 civilian cases of encephalitis lethargica were notified in England and Wales in the fifty-two weeks ended November 3rd 1928. He could not state what was the number of cases in which vaccination had been performed within two months of the appearance of the disease, as medical practitioners were not required to state the vaccinal condition of persons notified as suffering from this disease. Dr. DAVIES asked whether other zymotic diseases had not been followed by encephalitis lethargica in which the question of vaccination did not arise at all. Mr. CHAMBERLAIN confirmed this. In answer to a question on November 20th the Minister of Health said the recent report of the Committee on Vaccination stated that almost all vaccine establishments used rabbits for the purpose of improving and maintaining the quality of the seed lymph. His department had no information as to any countries in which this practice was not followed, and he could not say, therefore whether those countries had displayed any special freedom from post-vaccinal encephalitis.

Maternity and Child Welfare.—Provision has been made in every sanitary district of the country either by the county council or the local sanitary authority for maternity and child welfare. Such provision is now made by 60 county councils, 83 county borough councils, 135 urban district councils and 18 rural district councils. After announcing these figures to the House of Commons on November 15th Mr. CHAMBERLAIN added that he knew the Association of Infant Welfare and Maternity Centres had passed a resolution against the proposed substitution of block grants in support of maternity and child welfare centres. Mr. Chamberlain hoped that the proposals now before the House would dispel any fear that these services would suffer by the changes fore-shadowed. Answering Mr. Montague on the same day Mr. Chamberlain denied that a circular had been issued to local authorities intimating a maximum expenditure which would be recognized for grant in aid of the supply of milk for expectant and nursing mothers and children. In the letters which were sent to some local authorities last March informing them of the maximum expenditure for maternity and child welfare work during the current financial year which could be recognized for grant, suggestions on procedure were made with a view to enabling the authorities to keep their expenditure on milk within the amounts approved for grant. This letter was sent only to the authorities whose estimated expenditure on milk exceeded £100 and, moreover, was not addressed to those whose districts are situated in distressed mining areas in Durham, Lancashire, Northumberland, and South Wales. The total estimated saving in grant was about £12,000.

Pulmonary Tuberculosis and War Service Conditions.—In reply to Dr. Vernon Davies on November 15th Mr. A. M. SAMUEL said the Joint Medical Committee consisting of the directors of medical services of the three service departments and the Ministry of Pensions, were investigating the attributability of pulmonary tuberculosis in the defence forces to the conditions of service. A report on the relationship between these conditions and pulmonary tuberculosis had been prepared for this committee by a subcommittee and was being considered. He could not anticipate the conclusions of the committee. Answering Sir Arthur Shirley Benn on the same day, Colonel HEADLAM said the Board of Admiralty had made careful and exhaustive inquiry into the incidence of tuberculosis in the navy with particular reference to the question whether in pension awards following invaliding for this disease, there was adequate recognition of causes peculiar to the conditions of naval service afloat to which tuberculosis might be regarded as attributable. As a result of this investigation they had come to the conclusion that although the rules and principles governing the assessment of attributability in tuberculosis cases had in the past been correctly formulated there were grounds justifying more generous treatment in many of these distressing cases and they had decided that in respect of invalidings as from October 1st 1928 there should be such a modification of these rules and principles as would considerably reduce the percentage of cases in which non-attributability

awards only could be regarded as appropriate. These arrangements were without prejudice to the consideration of any recommendations which might be embodied in the report on this question which was expected shortly from the Joint Medical Services Committee.

Treatment of Tuberculosis under the Public Health Act—Mr CHAMBERLAIN told Mr BELLAMY, on November 15th, that he did not know any local authority which had not made adequate arrangements for treatment of tuberculosis under Section 1 of the Public Health (Tuberculosis) Act, 1921. Provision of sanatorium accommodation was still in progress. He anticipated that this would be helped by the passing of Poor Law accommodation into the hands of counties and county boroughs. As regards village settlements for the after-care of persons who had received sanatorium treatment further experience was needed before any extensive development could be expected.

Lighting of Schools—Sir CHARLES TREVELYAN asked Lord EUSTACE PERCY on November 14th why the Board of Education recently insisted on certain local education authorities putting into their schools windows admitting direct sunlight. Lord EUSTACE PERCY said these authorities had proposed to erect premises into which direct sunlight could never penetrate. There had been no unreasonable interference with the authorities' discretion and the rigidity of the Board's building regulations had been greatly relaxed during the last three years. In the schools in question it would still be possible by use of blinds to exclude direct sunlight when desired.

Artificial Light Treatment of School Children—Dr VERNON DAVIES on November 15th asked what steps the President of the Board of Education took to provide that artificial light treatment for the school child was only given by properly qualified persons. Lord EUSTACE PERCY said that in many cases artificial light treatment for children attending public elementary schools was provided at the light department of a general hospital under an arrangement between the local education authority and the hospital authorities. Treatment at a school clinic was allowed only on condition that the medical officer with special experience of artificial light therapy was in charge, assisted by a nurse who also had special experience of this work.

Radio-therapeutic Treatment of Disease—On November 19th Sir KINGSLEY WOOD told Dr VERNON DAVIES that the Ministry of Health was responsible by means of grants or otherwise for the use of electrotherapy in the treatment of disease. Electrotherapy was practised in public institutions dealing with tuberculosis with maternity and child welfare and with the care of the pauper sick. It was a condition of any grant that the medical officer using such means of treatment should be especially qualified or experienced and the treatment provided in a Poor Law institution was always under the direction of a qualified practitioner. In reply to a question regarding the supply of radium Sir KINGSLEY WOOD stated that the radium requirement of this country in relation to present sources of supply was under consideration by a subcommittee of the Committee on Civil Research. He hoped the report of the subcommittee would be presented shortly. Colonel WOODCOCK asked if in the meantime the Ministry would allow institutions to purchase radium on the same terms as they had already permission to purchase. Sir KINGSLEY WOOD replied that he did not think that arose out of the question.

Ultra violet Light Statistics—Mr CHAMBERLAIN has promised to consider a suggestion that he should recommend all local authorities to publish daily statistics of ultra violet light similar to those now issued by the National Institute of Medical Research, Hampstead and at four other places.

Factory Inspectorate—In an answer to Mr BUCHANAN on November 15th Sir WILLIAM JOYNSON HICKS said the Committee appointed to inquire into the question of the factory inspectorate had only recently commenced its work. He did not think it necessary to ask for an interim report.

Shortage of Hospital Beds at Newington Poor Law Institution—Mr NEVILLE CHAMBERLAIN in answer to a question said he was aware that additional accommodation was required at the Newington Poor Law Institution where a shortage of hospital beds was alleged. He was unable to approve a scheme submitted by the Southwark board of guardians involving an expenditure of £100,000. Officials of the Ministry had made suggestions to meet the immediate needs of the institution.

Hop-pickers Accommodation—Mr CHAMBERLAIN in an answer to Mr BRIANT on November 15th said he had received reports on the condition of hop-pickers in the recent season. On the whole these showed that satisfactory progress was being made by the district councils in securing a proper standard of accommodation. He did not contemplate transferring this responsibility to a central authority.

Foot and Mouth Disease—From August 1st to November 15th twenty-five outbreaks of foot and mouth disease were confirmed in Great Britain. Mr GUNNESS stated that the work of the Foot and Mouth Disease Research Committee was being continued in five different laboratories and that the Pirbright Experimental Station had been refitted for work on an extended scale on the larger animals. On November 19th he informed General WRIGHT that in connexion with the outbreak of foot and mouth disease in Devonshire no report had been made to him of the danger that the Ministry's inspectors might spread infection by not changing or disinfecting their clothing as well as their boots when moving from an infected into a non-infected area. Every inspector of the Ministry was required to wear special waterproof overall clothing when engaged on foot and mouth disease duties and to disinfect the whole of his clothing and his hands at the time of entering and leaving premises. Experience proved that the precautions were

adequate, and he was satisfied that the inspectors did not spread the disease. The Ministry considered that the policy of slaughtering animals affected with foot and mouth disease and exposed to infection was the only policy which with the existing knowledge of the disease would be successful in preventing it from becoming endemic in this country. The first animals affected in the serious outbreaks which had recently occurred in the neighbourhood of Plymouth were pigs which had been fed on swill containing scraps of meat of foreign origin. The swill had not been boiled in accordance with the Foot and Mouth Disease (Boiling of Animal Foodstuffs) Order 1923.

Award of Pensions to Ex-Servicemen—Mr BALDWIN in a reply on November 15th to Sir ARTHUR HOLLBROOK said he had received a memorandum from the Annual Conference of the British Legion advocating the co-ordination of the award of pensions to ex-members of the fighting services, and the placing of the responsibility for dealing with pensions for all the forces of the Crown under the Ministry of Pensions. Mr BALDWIN said he was satisfied, after consulting his colleagues that there would be no real advantage, but serious disadvantages in such a step.

Smoke Abatement—Mr CHAMBERLAIN told Commander BELLAMY on November 20th that under the Public Health (Smoke Abatement) Act 1925 there were now five regional advisory committees including one for Greater London and one executive committee with administrative powers. An order had been made bringing new processes under the operation of the Alkali Act. By laws as to the emission of black smoke had been approved for a number of local authorities and generally there was a marked quickening of interest and activity in the work of smoke abatement.

Proposed School for Mentally Defective Children—On November 19th Lord EUSTACE PERCY in reply to Mr CRAWFORD denied that a proposal of the education authorities of Middlesex, Ealing, Brentford and Chiswick, Heston and Isleworth and later Twickenham, to open a day school for mentally defective children had been refused. The Board of Education had, however, suggested that the proposal should be deferred pending the report of the Special Committee on Mental Deficiency which he hoped to receive soon.

Notes in Brief

Since October 1st 1924 sixty sluice clearance schemes involving rehousing of 35,000 persons have been confirmed. Eight of these schemes have been completed and the population rehoused.

No cases of adverse effect on health from the prohibition of the use of food preservatives have been brought to the notice of the Minister of Health who sees no reason to modify the new Preservative Regulations.

The Ministry of Health hopes soon to issue a report on refuse dumps.

Asked as to what progress had been made by the Joint Medical Services Committee of the Navy, Army, and Air Force in establishing a common system of costing for hospitals Mr A. M. SAMUEL said the matter was still under consideration.

Medical News.

The annual dinner of the Medico-Legal Society will be held at the Holborn Restaurant, London, on Friday, December 14th, at 7.15 p.m., with the president, Sir WILLIAM WILCOX, in the chair.

The tenth annual reunion dinner of the 29th General Hospital will be held at the Trocadero Restaurant, London, on Saturday, December 8th, at 7.30 p.m. Applications should be addressed to the Secretary, Heatonfield, Meadowcourt Road, Leicester.

The sixteenth annual meeting of the British Dental Hospital will be held at 23 Russell Square, W.C., on Thursday, November 29th, at 8 p.m. with the president Sir Harry Baldwin, in the chair. Dr Leonard Williams will give an address on the arch of the buccal building.

The Fellowship of Medicine and Post-Graduate Medical Association announces that on Monday, November 26th, Dr Donald Paterson will give a lecture on "Some problems in infant feeding," at the Medical Society of London, 11 Chandos Street, Cavendish Square, at 5 p.m., and on the following Wednesday Mr Victor Bonney will give a "Gynaecological talk," at the Medical Society, at 11 a.m. Demonstrations will be given on Thursday, November 29th, at 4 p.m., by Mr Cunningham, at the Central London Ophthalmic Hospital, and on Monday, November 26th, at 2.30 p.m. by Dr A. J. Whiting, at the Prince of Wales's General Hospital, Tottenham. There is no fee for the above lectures and demonstrations. Special courses are in progress in urology at St Peter's Hospital, in ophthalmology at the Royal Westminster Ophthalmic Hospital, in neurology at the West End Hospital for Nervous Diseases, and in venereal diseases at the London Lock Hospital. During December there will be two courses only, from December 3rd to 15th, in infants' diseases at the Infants Hospital and in dermatology at the Blackfriars Skin Hospital. Copies of all syllabuses and information regarding the general course arranged by the

Followship of Medicine will be sent on application to the Secretary, 1, Whitpole Street, W 1. The complete list of medical courses for 1929 is now ready.

The Society of Apothecaries of London held its Anniversary Dinner on November 20th in the Hall at Blackfriars. The guests were received by the Master, Lieut Colonel C. T. Samman, R. A. M. C. (ret.), and the Wardens, Dr H. J. Hott and Sir George Buchanan. The toast of the Royal Colleges was proposed by the Immediate Past Master, Dr R. Whitosido Slatham, who took this opportunity to compliment the President of the Royal College of Physicians on the brilliant success of the Harvy torrentary celebrations carried out under his leadership. Sir John Rose Bradford, P. R. C. P., in reply, expressed his pleasure in enjoying once more the hospitality of the Society, between whom and his College there were many links besides their common aim in regard to medicine. Sir John Lynn Thomas, as an old friend of the Master, was warmly welcomed when rising to reply on behalf of the Royal College of Surgeons, in the course of a brief speech he congratulated the Society on instituting its new Diploma in Midwifery and Child Welfare. The toast of "The Anniversary" was proposed by the Master, who said that for more than 300 years the Society had held to the old traditions of the medical City Guilds, promoting the well being of its members and encouraging good workmanship among them. He added that the woodwork of the Society's Hall—as many of those present know too well—had been ravaged by the death watch beetle, as investigation proceeded worse and worse damage came to light, so that a large part of the old building would have to be rebuilt, brick by brick and beam by beam. The Master ended by presenting a beautiful silver salver, bearing the names of many subscribers, to the Bedell, Mr William T. Withers, who has been the trusted servant of the Society for a great number of years. Mr John F. Eastwood replied on behalf of his fellow Leomen, and Mr Withers acknowledged the gift. The concluding toast was that of "The Guests," proposed by the Junior Warden, Sir George Buchanan, and replied to by Sir St. Clair Thomson and Mr Charles Branch, Master of the Vintners Company.

INFORMATION regarding the International medical tour of the Côte d'Azur, arranged by the Société Médicale du Littoral Méditerranéen to take place after Christmas, may be obtained from Mme Juppe Blaise, Federation of the Health Resorts of France, 1, Gordon Square, W. C. 1, or from Dr M. Faure, 24 rue Vordil Née. Particulars of the programme were given in the *Journal* of October 13th (p. 682), the party assembles at Marseilles on the evening of December 26th, proceeding thence to London, Cannes, Monte Carlo, Mentone and other centres, where scientific demonstrations, therapeutic discussions, visits to places of interest, and entertainments will be arranged. The tour ends on January 7th at Nice, after an excursion to the Alps but members who so desire may extend their journey to include a visit to Corsica.

LIEUT. COLONEL A. E. HAMERTON, D. S. O., late R. A. M. C., has been appointed pathologist to the Zoological Society of London, in succession to Dr H. H. Scott, who has taken up an appointment under the Colonial Office.

The following members of the medical profession were called to the Bar on November 19th: Dr Eric W. C. Thomas (Middle Temple), Dr W. H. Bntcher and Dr V. P. Gonsalves (Inner Temple).

THE Professional Classes Aid Council in its seventh annual report covering the year ended April 30th 1928, takes occasion to explain the reasons for its existence side by side with the many benevolent funds maintained by the various professions. It is pointed out that experience has shown many persons do not know of such special funds, and that these funds are still less known to widows and other dependants. The regulations which govern their administration, moreover, often restrict severely their scope and functions, while there are, further, educated people of the class termed the "new poor" who have no claim on any other funds. No defence of the council's position, however, could be so convincing as proof of the necessity for its existence as its record. Last year 780 applicants were dealt with and financial help was given to 154 families. A very considerable number (334) were advised to apply for help to other agencies, and directed how to proceed in this way the council acted as a clearing house for information and provided a link between applicants and the societies concerned. It has also been able to co-operate with certain other organizations in supplementing the funds at their disposal in special cases. In giving relief the Council seeks to adopt the form best calculated to rescue the applicant from future difficulties. The largest item in its relief expenditure was education: the school expenses of 58 children have been wholly or partially met. Other persons have been assisted to obtain professional training, and a number have

been given relief in emergencies caused by illness, etc. During the past year, through the kindness of an anonymous donor, who has undertaken to place a sum of £500 annually at the disposal of the Council, it has been possible to provide annual allowances for aged and infirm persons. The Council is composed largely of representatives of the leading professional bodies and benevolent organizations: the British Medical Association being represented by its Treasurer, Mr N. Bishop Harman.

VARIOUS sections of the ninth annual report of the Scottish Board of Health, 1927, of which a summary appeared in our issue of June 23rd, 1928 (p. 1081), have now been issued separately in pamphlet form, and are obtainable at His Majesty's Stationery Office or through any bookseller. We have received copies of the following: *The Problem of Puerperal Sepsis* (3d net); *The Work of the Medical and Dental Referees under the National Health Insurance Act* (4d net); *The Pollution and Purification of Rivers* (6d net); and *The Poor Law Medical Service* (4d net).

THE fourteenth annual report of the British Gynaecological and Maternity League states that abnormal weather conditions in 1927 favoured an increase in malarial disease, causing higher infant and child mortality. By means of propaganda and of the supply of food, clothing, and mosquito nets the league is endeavouring to prevent this wastage of young life, and the settlers, aboriginal Indians, and others are, it appears, learning to appreciate the value of its work. During 1927 the league nurses attended 2,661 confinements, as compared with 563 in 1918. The development of ante-natal work has proved difficult, and in some districts expectant mothers have been found very reluctant to attend clinics, although the prevalence of malaria, nephritis, and pyelitis, and other complications makes it important for them to have medical inspection. It is suggested that there is an urgent need for propaganda in connexion with pre-natal care among the parents and the midwives in the villages.

DURING 1926-27 the number of grants made by the Queen Alexandra Sanatorium Fund, which exists to help tuberculous patients of limited means to obtain treatment at Davos, was again greater than in any previous year. Payments at the rate of £2 (50 Swiss francs) a week are made to selected patients in an early stage of the disease grants being given for a period covering the late autumn, winter and early spring conditional on the patients staying at approved sanatoriums or pensions at Davos. This grant system, which was adopted quite recently, has proved generally satisfactory. Many patients, however, have not derived the maximum benefit from the treatment owing to the shortness of their stay. The honorary secretary of the fund is Mr D. Vesey, 97, Warwick Road, S. W. 5.

THE Marengo prize for 1928 has been awarded by the College of Physicians of Philadelphia to Drs J. R. Paul and W. N. McClellan of Philadelphia, for their essay entitled "A pathological study of the pleural and pulmonary lesions in rheumatic fever." The next award of the prize, which amounts to about 300 dollars, will be made on July 14th 1929. Essays submitted may be on any subject in medicine, and must represent an addition to knowledge based upon original or literary research: they must be received by the Secretary of the College of Physicians, 19, South 22nd Street, Philadelphia, Pa., U. S. A., on or before May 1st, 1929.

ON attaining his eightieth birthday and in recognition of his public services, Dr William Smith Paget Tomlinson was, on November 19th, the recipient of presentations from the inhabitants of Kirby Lonsdale and from his farm tenants there. Receiving his medical education at Liverpool and University College London, Dr Paget Tomlinson graduated M. B. Lond. in 1871 and proceeded M. D. in 1879, he was elected a Fellow of the Royal College of Physicians in 1927. He has served as chairman of the Westmorland School Medical Inspection Committee and of the Public Health Committee, and is president of the Westmorland Sanatorium for the Consumptive Poor, for the establishment of which he was mainly responsible. In 1897 he was High Sheriff of the county.

SIR ROBERT ARMISTEAD JONES of Plas Dinas and Dr J. H. Morris Jones of Colwyn Bay have been nominated as sheriffs for Carnarvonshire and Denbighshire respectively.

THE forty-fourth German Balneological Congress will be held in Berlin under the presidency of Professor Dietrich, from January 25th to 27th 1929 when the principal subject for discussion will be science and research in balneology.

In memory of her brother Mr Nathaniel M. Barnes who was for many years a member of the committee of Bolton Infirmary, Mr A. Barnes has given £10,000 to that institution. The money will be used to build the first of four new hospital blocks.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are *MUSEUM 9361, 9362, 9363, and 9364* (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are
EDITOR of the *British Medical Journal*, *Antiology Westcent, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements, etc.), *Articulate Westcent, London*

MEDICAL SECRETARY *Mediscera Westcent London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Bacillus, Dublin*, telephone 62550 Dublin) and of the Scottish Office, 7, Drumshigh Gardens Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

QUERIES AND ANSWERS

DELAYED MENSTRUATION

Dr U. BAYLIS ASH (Birmingham) writes with regard to the inquiry by A. E. (November 3rd p 823). I saw a similar case successfully treated by Dr Urbach of the Wilhelmsplatz, Vienna. He used diathermy the electrodes being placed on either side of the head, and the skull and its contents were warmed. This girl after a number of treatments, lost weight and began to menstruate. Before this treatment commenced it would be advisable to have a skiagram of the skull to show any possible abnormality of the pituitary fossa.

INCOME TAX

Married Couple Living Together

"H. M. H." explains that the wife runs a house in which both live, the husband pays her £10 a month, and also pays two-thirds of the household expenses the King's taxes (Income Tax both A) on the house and shares the payment of local rates with the wife. Is the wife liable to account for tax on the £10 a month?

*. No. The incomes of husband and wife are aggregated for the purpose of calculating tax so that a payment by one to the other should be ignored—unless, of course, the two are living apart. On the other hand, it follows that in calculating the amount of his professional income "H. M. H." cannot treat the rent as an actual payment but must calculate the amount of the deduction as a proportion of the annual value of the house as assessed to income tax.

LETTERS, NOTES, ETC.

THE QUAKERS AND MEDICINE

In a contribution to the *Bulletin of the Society of Medical History of Chicago* Dr David J. Davis of the University of Illinois College of Medicine Chicago has given a sympathetic account of the origin of the Quakers, in which he points out that of the four chief professions in the seventeenth century—the Church, Law, the Army and Medicine—the last was the only one which was at all consistent with their views of life. Both in England and in the United States there appeared a number of medical men who were either ardent Quakers or the descendants of such and to whom medicine and the world at large will be eternally indebted. Dr Davis considers them under two groups—namely a number of great English Quaker physicians and a line of physicians—largely of Welsh origin—who went to America early some with Penn himself. The first great English Quaker physician was Dr John Fothergill (1712-80) whose most important scientific contribution was his "Account of the sore throat attended by ulcers" describing the epidemic of scarlet fever which visited London in 1747. He was a close friend and admirer of Benjamin Franklin, and became interested in the American Quaker colonies in their early days. The first of the native Welsh physicians who accompanied Penn was Thomas Wynne (1631-92) who was afterwards not only the chief physician in the young colony of Philadelphia, but also a

prominent person in public affairs. His daughter married Dr Edward Jones, another notable Welsh physician and from them were descended two men whose names are of importance in American medicine—Thomas Cadwalader the first teacher of medical anatomy in America and author of an essay on "West Indian dry gripes" (laid colic), and John Jones, whose *Plain Remarks upon Wounds and Fractures* which appeared in 1775 was the first book on surgery published in the United States and probably the first medical book of any kind written by an American. John Jones was also an intimate friend and physician of both Benjamin Franklin and George Washington. The last of the prominent medical men of Quaker birth in America was Dr John Evans commonly known as Governor Evans (1814-97) who was editor of the *North Western Medical and Surgical Journal* (the first medical journal in Chicago), co-founder of the American Aged Association and professor of obstetrics in Rush Medical College. In conclusion, Dr Davis summarizes the influence of Quakers in medicine under two heads. In the first place they furnished great practitioners of medicine in such men as Fothergill, Lottson, Wynne Jones and Lister, and secondly they showed a genius for organization, which was exemplified by John Morgan (the founder of the medical school in connexion with the College of Philadelphia), Evans, and John Hopkins.

IMPOUNDABLE PHOSPHORUS THERAPY

Dr M. J. T. WALLIS (Maldon, Essex) writes. All scientific persons whether medical men or otherwise, will be astonished and incidentally vastly amused, at the coroner's summing up at a recent inquest. It was the case of a man, aged 75 who died of cancer of the stomach shortly after taking some powders which had been given him by an unqualified practitioner. This gentleman had seen him once and charged him fifteen guineas. The powders on analysis were found to be quite harmless, only cane sugar being detected. The unqualified practitioner stated that they contained "phosphorus in unobtainable doses." This towering genius expert analytical chemists will be pleased to hear, has made over a thousand drugs of which no trace can be detected by either chemical or spectroscopic means.

Now this I submit is a very nasty snipe at the chemists. We wretched mediocrities of doctors, with our admittedly inexact science, who have been foolish enough to spend from five to seven years studying the elements of our subject, who on making any advance in medicine or surgery are foolish enough to disseminate that knowledge among our colleagues and who generally charge the patient about half the number of shillings that the saccharine and non-tangible phosphoric gentleman charged guineas, and who quite humbly realize that we are only on the very fringe of knowledge on these matters—we medical men, I say, are getting quite tired of having pointed out to us in the press how very narrow bigoted and stereotyped we are how saturated with professional jealousies and how unwilling we are to admit that wisdom will not die with us. But what have our chemists been doing all these years not to have made any of these elusive, non-tangible and apparently very expensive substances that cannot be detected by any of their childish tests? Surely they must share in our ignorance on this occasion.

The effects of the coroner's summing up on the public mind (I am not for a moment overlooking the verdict, which was the obvious one) were these: to give a colossal advertisement for all forms of unqualified medical practice, to stimulate Mr. Bernard Shaw to a further outbreak of juvenescence, but unfortunately, to have a very harmful effect on the minds of sufferers from this terrible disease. In legislation regarding matters of this kind we are of course, fifty years behind America and all civilized European countries. Should not a technical expert sit by the coronor or judicial authority in an advisory capacity in such cases to save him from emitting egregious folly on a subject of which he is profoundly ignorant? To my mind the long continued reticence of the medical profession on these and similar matters is most emphatically not in the public interest.

TUBERCULOSIS SERVICE.

Dr F. J. ALLAN (Chairman of the Medical Sickness Annuity and Life Assurance Society Ltd.) writes. Dr A. J. McMillan suggests in his letter in your issue of October 20th (p. 727) on the subject of the tuberculosis service, that the county or other administrative body should take out a sickness insurance policy on the life of each person appointed to such service. It may be of interest to your readers to know that this society has worked on a scheme which has been adopted by a tuberculosis hospital to meet the point raised. Under this it is compulsory for each resident medical officer on taking up his appointment to effect the policy with this society the premium for which is paid by the administrative body. Special rates are charged and various options provided so that the policy may be retained by each individual on leaving the service.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 45, 46, 47, 50, 51 and 52 of our advertisement columns and advertisements as to partnerships, assistantships, and locum tenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 235.

Remarks

OF

DRAINAGE OF BRAIN ABSCESS *

BY

SIR PLEROY SARGENT, CMC DSO, I RCS,
Senior Surgeon, St. Thomas's Hospital

THE general principles of treatment of abscess of the brain differ in no essential feature from those which obtain in abscesses elsewhere in the body, but the peculiar characters of the cerebral tissue, the existence of the cerebro-spinal fluid circulation, and the physical conditions of pressure within the cranial cavity create special difficulties and problems. While the primary object in dealing with these cases is the effective drainage of the abscess, yet the possibility of fatal complications following precocious or misdirected surgical measures, together with the dangers of serious damage to brain function, must be given due consideration in planning the operation.

The great variations of type which occur among cerebral abscesses, from a diffuse septic softening right down to an encapsulated mass of almost solid fibrous tissue, are apt to create confusion when treatment is being discussed, for measures clearly right for one variety may be obviously wrong for another. The frequent coexistence, especially in otitic cases, of other infective complications, meningitis, ventricular ependymitis, and sinus phlebitis, tends still further to confuse the issue.

In discussing the treatment of abscess of the brain, and especially perhaps in speaking of results, it is necessary to be quite clear as to the type of case with which we are concerned. Although the various kinds of abscess merge into one another, certain types can be recognized: (1) diffuse septic softening, (2) a pus-containing cavity with ragged wall consisting of softened brain tissue, (3) a cavity with a thin capsule consisting of young fibrous granulation tissue, (4) a cavity, perhaps small in relation to the size of the abscess, consisting of dense fibrous tissue, which may be the greater part of an inch in thickness.

In the first variety, which is not really an abscess at all but a diffuse infective encephalitis, comparable with a cellulitis of the connective tissues, no surgical treatment is likely to be of any use, except perhaps a simple decompression.

When, however, as in the second class, this encephalitis is of a somewhat less virulent type, and necrosis with pus formation has occurred in its central part, drainage may be undertaken with some hope of success. This is a type of abscess which during the war was not infrequently encountered in the track of a shell fragment. The most intense septic reaction was apt to be found near the point of entrance, as if the most heavy microbial infection as well as the maximum devitalization of tissue existed just beneath the aperture in the skull, as indeed one would expect to be the case in abscesses developing months or years after such wounds the same rule holds.

The third and fourth types differ chiefly in the thickness of the capsule, and naturally they merge perceptibly into one another. At one end of the scale there is a thin capsule varying, however, in thickness at different places, while at the other end is an almost solid mass of fibrous tissue containing perhaps but a few drops of pus. Around the thinnest-walled abscesses there is an area of oedematous brain, in which, naturally, extension may take place. By this route the ventricle may become involved.

With the very chronic thick-walled abscesses the changes in the surrounding brain may be inconspicuous and insignificant. In such cases the question of drainage scarcely arises, the proper treatment is complete enucleation, with closure of the wound. I have had five such patients, all of whom recovered. In one other similar case drainage was necessitated by the fact that, just as the mass was being delivered, a thin part of its wall gave way,

causing soiling of the wound. This patient also recovered completely.

This discussion, however, is chiefly concerned with what is perhaps the commonest type of abscess—a cavity containing some drachms, or even ounces, of pus bounded by a relatively thin capsule, which in its turn is surrounded by an area of soft oedematous brain. Most of these are of otitic origin, and are situated either in the temporal lobe or in the cerebellum. The cerebellar cases are apt to present earlier indication of their presence because of the ventricular distension to which they tend to give rise. They are therefore likely to be operated upon at an earlier stage.

It is instructive, I think, at this point to recall the very remarkable series of cases upon which Macewen bases his classical monograph (1893). In Table III the astonishing figures are given that of 19 patients operated upon 18 recovered. No wonder Macewen was able to write, cautions Scot though he was, "One might almost conclude that in uncomplicated abscess of the brain, operated upon at a fairly early period, recovery ought to be the rule." His recovery rate is, as Mr. Miles Atkinson pointed out recently (*Lancet*, March 24th, 1928), much the same as the mortality rate of many other surgeons. Not only, as he says, has no one been able to improve upon Macewen's successes, but no one has ever been able even to approach them.

A perusal of Macewen's detailed yet lucid account of his cases brings out the fact that he was dealing with one particular group—namely, the definitely encapsulated abscesses with a long history, and usually containing a large amount of pus. The average duration of the illness before operation was, in the twelve cases in which it is stated, no less than seventy days. Macewen's cases at least lend no support to any plea for precocious operation. Early operation, however, as soon as the presence of an abscess is definitely diagnosed, must be undertaken, for the risks of delay are great. The chief dangers are rupture into the ventricle, rapid onset of cerebral compression from oedema, and, in cerebellar cases especially, sudden respiratory failure.

A spreading abscess tends to make its way towards the ventricle, or rather, perhaps, the ventricle filled with fluid under pressure tends to herniate into the softened brain.

This is also true after an abscess has been imperfectly drained, and in such cases the accident not necessarily fatal, of a communication being established between abscess and ventricle is marked by the escape of cerebro-spinal fluid from the wound.

When an abscess has been properly evacuated and drainage established the intracranial pressure falls, provided that no complication exists such as meningitis, encephalitis, or a second abscess. The appearance of a fungus cerebri means that the intracranial pressure has not been relieved. A "fungus" must be clearly distinguished from a "hernia" cerebri. The latter means a protrusion of healthy brain, still covered by pia arachnoid and skin, with its circulation and functions unimpaired; a fungus is a protruding mass of strangulated necrotic and functionless tissue indicative of unrelieved intracranial pressure.

In operating for cerebral abscess the two most important technical considerations are the route to approach and the method of drainage. Ballance has frequently called attention to the fact that with abscesses originating in bone disease, as most of them do, there is a stalk, representing the inward track of the infection, connecting bone and abscess; this should furnish the ideal route of approach. The membranes are presumably adherent at this spot, so as to seal off the subarachnoid space. In otitic cases the surgeon, during the mastoid operation, may be fortunate enough to find the stalk, and it is possible that the drainage so established may be adequate. Several of Macewen's cases at any rate were successfully treated in this manner.

Failing this, the transarachnoid route must be adopted. The bony opening need not be a large one as the evacuation of the pus will be followed by a fall in intracranial pressure. This diminution of pressure, it must be remembered, is followed immediately by a falling away of the brain from the surface, with the consequent opening up of

* Made in opening a discussion in the Section of Laryngology and Otology at the Annual Meeting of the British Medical Association, Cardiff, 1923.

the subarachnoid space. It is therefore necessary, before evacuating the pus, to shut off the subarachnoid space by strips of gauze tucked in beneath the dura, these guarding plugs may be left *in situ* for two or three days, just as is sometimes done in the transplasmal drainage of a hepatic abscess, or the transperitoneal drainage of an abdominal abscess.

The presence of a subcutaneous abscess is usually indicated by bulging of the brain, with pallor, broadening and softness of the exposed convolutions. If the abscess has deeply these characteristic appearances may be lacking. Exploration with trocar and cannula is, in my opinion, to be deprecated. The instrument may pass by the capsule, or, failing to penetrate it may push it towards, and cause it to burst into, the ventricle. My own practice is to use a small flat seeker, which passes with the least possible force through the softened brain tissue, and with which the resistance of an abscess wall can easily be felt. If by chance the instrument penetrates into a thin-walled abscess, pus at once flows out along it. The abscess having been thus located, I tie off such cortical vessels as may be necessary, and make a clean incision into the abscess with a sharp knife. The material of which the tube is made is of little importance provided it has sufficient rigidity, a rubber tube is rather too bulky for the size of its channel, but usually serves the purpose well enough. I have from time to time used tubes made of aluminium or of celluloid. MacEwen employed decalcified bone tubes. Matters of greater importance concern the after-treatment. The tube, which should have been sutured to the edge of the dura or skin, must be kept clear by frequent gentle syringing, and should be retained in place for a long while, at least until all tendency for the brain to protrude has disappeared. It should be shortened only very gradually. If the brain protrudes persistently or increasingly either the abscess is insufficiently drained or some complication such as a second abscess or meningitis may be present. It is unwise, however, to interfere locally too soon, as there is always some oedema which tends to push the tube out. This period can be tided over by withdrawing fluid from time to time by lumbar puncture.

A British Medical Association Lecture

ON

SOME DISORDERS OF THE LYMPH GLANDS

BY

A. F. GOW, M.D., F.R.C.P.,

PHYSICIAN IN CHARGE OF OUT PATIENTS ST BARTHOLOMEW'S
HOSPITAL

THE lymphatic system consists of a widespread set of vessels, most abundant in the skin, the intestine, and the connective tissues, in the course of which are aggregations of lymphoid tissue, termed lymph glands or nodes. The lymphatics take origin in the tissue spaces as capillaries. They are provided with valves, and drain into nodes arranged for the most part in groups, from which arise larger efferent vessels, these pass to one or more groups of nodes situated more deeply, and discharge ultimately into the main lymphatic channels—namely, the thoracic duct and the right lymphatic duct, which open into the origin of the innominate vein on the left and right side respectively.

In addition to the lymph nodes, lymphoid tissue is widely distributed throughout the body. The tonsils, including the pharyngeal tonsil, the thymus, and the spleen are composed almost entirely of this tissue, the alimentary tract is richly supplied with lymphoid elements, both as solitary follicles and as agglomerations in the lower part of the ileum (Peyer's patches), the appendix, and the colon.

The lymph nodes are collected into groups, of which the cervical axillary, and inguinal are the principal ones near the surface of the body. More deeply, there are important collections about the trachea in the root of the lung, in

the posterior mediastinum, in the transverse fissure of the liver, along both sides of the spine in relation to the aorta and its main branches, and in the mesentery. Over and above these are sundry collections and single nodes the existence of which is scarcely appreciated until they are enlarged as the result of disease, examples are the epitrochlear, infraclavicular, and preauricular nodes.

It is by the lymphatics that certain substances are drained away from the tissue spaces with the help of phagocytic cells. Fat is absorbed from the intestinal villi into the lacteals. The chief functions of the lymph nodes are to produce lymphocytes, and to form a barrier against infection of the more important tissues of the body. Not only microbes, but particles of soot, dust, and even neoplastic cells, are caught by this means and held back from the general circulation, no doubt many diseases of an infective nature abort at this line of defence. Lymphatic glands, then, are open to attack either by way of the lymphatics or of the blood stream.

Lymph nodes enlarge as the result of inflammation, of hyperplasia, or of infiltration by blood cells or new growth. An important series of changes, again generally associated with enlargement, is that which signifies retrogressive processes in the nodes, examples are fibrosis, caseation, the deposit of foreign substances, and abscess formation.

Lymph nodes in health are usually impalpable, and, unless the patient is unusually thin, nodes which can be definitely felt must be assumed to be pathological.

When investigating the lymphatic system of a patient in whom any enlarged nodes are found, the first inquiry is upon an anatomical basis in what group or groups is the enlargement present? The superficial nodes are examined systematically by careful inspection and palpation. Moderate enlargement of the cervical nodes may cause some fullness of the neck, the recognition of this feature may call attention to the presence of soft glands—as, for example, in acute leukaemia—which otherwise might escape detection. Stiffness of the neck, and perhaps torticollis, may be associated with enlarged cervical nodes, so also may a neuralgia accompanied by tenderness and hyperaesthesia of some part of the scalp or a headache which arises in the neck and spreads upwards over the vertex. In the axilla, care must be taken not to mistake fat for enlarged nodes. Sometimes superficial nodes in unusual places are to be seen or felt—for instance under the scalp, near the zygoma, and in the intercostal spaces. Of the deep groups, those within the abdomen when sufficiently enlarged may be recognized by palpation, or by signs of pressure upon neighbouring structures to which they give rise—as, for example, to jaundice with ascites when those in the transverse fissure of the liver are affected, and, be it remembered, multiple tumour formation within the abdomen is most often associated with lymphatic glands. It should also be borne in mind that an "odd" tumour within the abdomen—odd perhaps in regard to its characters or to the symptoms or lack of them, to which it gives rise—is not seldom of lymphatic origin. An examination of the blood in such cases must always be made, lest a laparotomy be performed unwittingly in a case of, say, chronic leukaemia.

When disease of the lymph nodes has led, as in the case of tuberculosis, to caseation or to calcification, such nodes may frequently be demonstrated by x rays, and so the cause of indefinite abdominal pains, perhaps associated with more or less pyrexia may be cleared up. Should caseous glands, as revealed by palpation and/or radiography, be situated mainly in the right iliac fossa, the portal of entry is most likely the appendix. Less often it is the Fallopian tube. In either case, when associated with symptoms, laparotomy is indicated for removal of the offending structure.

Lymph glands within the thorax cannot be detected by ordinary physical examination, save when they are very considerably enlarged and coalescent. When this is so, however, they may give rise to certain physical signs. Greatly enlarged lymph nodes in the anterior mediastinum may cause a visible tumour in the sternum, with percussion dullness upon veins. A similar state of things in the posterior mediastinum may yield impaired percussion resonance in

the spaces between the vertebral border of the scapula and the spine. Weak breath sounds, with or without bronchial breathing, may also occasionally be present. These signs, however, are uncommon, and are only to be expected when the glandular enlargement is considerable. When present, they are probably caused as much by collapse of lung, or by actual infiltration of the organ by the same tissue as is concerned in the glandular enlargement, as by the nodal swelling itself. In the earlier stages of glandular enlargement within the thorax recourse must be had to a ray examination, performed both in the antero-posterior and in the oblique positions, this investigation should always be undertaken in cases in which lymph nodes elsewhere are enlarged by a disease which is known to cause general lymphatic enlargement.

I.—Local enlargement results most often from local infection, the materials morbi being conveyed by the lymphatics. The area drained by the particular group enlarged must therefore be searched for the portal of entry. Local enlargement of nodes in the neck is very common especially in children, the reason no doubt being that foci of infection are so frequent in the tonsils, teeth, nasopharynx, and scalp. This is so whether the infection is pyogenic or tuberculous. In an adult, in the absence of an obvious inflammatory focus, the possibility of metastatic deposits must be considered, seeing that carcinoma of the tongue and of the oesophagus are frequent diseases. If a gland is felt in the left supraclavicular fossa and none higher in the neck, a metastatic deposit from a carcinoma of the stomach or a retroperitoneal sarcoma must be thought of. Glands in the cervical group of one side, again in the absence of gross local infection, are generally the first to be enlarged in Hodgkin's disease.

In a case of acute axillary gland enlargement it is likely that this results from infection of the hand, in which case there may be red streaks extending up the arm, due to lymphangitis. The local wound on the finger may be a seemingly trivial affair—a prick by a rose thorn or by a needle. The infection, which develops with great rapidity, is mostly due to *Streptococcus pyogenes*, and it is in this class of case that sensitized *S. pyogenes* vaccine, combined with concentrated scarlet fever antitoxin, is proving so useful. Infection with *Spirillum minus*, the causal organism of rat bite fever, may also result in an acute local enlargement and tenderness of lymph nodes—in such case there is a history of the patient having been bitten by a rat, a ferret, or a kitten, usually on the hand, three to four weeks previously. The bite heals probably without incident, but with the onset of symptoms the site of the wound becomes red and painful, and pyrexia of a relapsing character develops. In a pyrexial period the whole limb may be swollen, and though the lymph nodes draining the area are those mainly affected there may be some generalized lymphadenitis; the specific rash may be found in the skin. This infection usually yields quite quickly to full doses of neobicharsivan given intravenously, so much so that if a suspected case does not respond to two doses of 0.6 gram, given at an interval of five days, it is improbable that the illness is due to this cause.

II.—In generalized enlargement when the nodes are found to be enlarged in two or more groups, the materials morbi may be conveyed by the blood stream, in some infections this general enlargement has a definite diagnostic value—e.g., for example, in glandular fever, in rubella in the septicaemia at secondary stage of syphilis, and in bubonic plague. Another disease suggested by the discovery of general lymphatic enlargement in childhood and adolescence is acute lymphatic leukaemia, but here the nodal swellings are by no means the major part of the process and may be relatively inconspicuous in comparison with the severity of the general state. If the glandular enlargement has arisen insidiously, and if the patient's general state is not acute, the probable explanation lies in the direction of such diseases as lymphadenoma, tuberculous, leukaemia and sarcomatosis. The differentiation of these conditions depends upon the specific features of the glands and certain general signs presented by the patient, including a consideration of the blood picture.

The specific features of enlarged glands calling for special note are the number and distribution within the group

the size, whether the glands are discrete or confluent, their mobility, involvement of the skin and surrounding structures, consistency, and sensitiveness. It is important to remember that nodes which are adherent to one another, or to surrounding structures, are the seat of a disease process which has spread through the gland capsule—as in tuberculosis frequently, acute pyogenic infection occasionally, and malignant disease—or that the affected nodes have been treated by irradiation. In chronic cases more or less enlargement of glands in several groups suggests lymphadenoma, chronic leukaemia, or lymphosarcoma. Of these three diseases chronic leukaemia gives rise to the least difficulty in diagnosis because of its distinctive blood picture, whereas lymphadenoma is the most difficult, seeing that there are no enduring criteria on which to rely.

Of chronic leukaemia there are two main varieties—chronic myelocytic and chronic lymphatic leukaemia. It is the patient suffering from the latter condition who is likely to consult his doctor because of swelling in the neck or axilla due to glandular enlargement. It is a disease of adult life and has, as a rule, an insidious onset. It may occur in elderly persons, in whom it is prone to be quite latent over a long period. All the superficial groups are apt to be affected but often unequally, the mass in the neck, axilla, or groin perhaps causing considerable deformity. The individual nodes in a group are of much the same size, soft rather than hard, discrete yet bunched up together, showing no tendency to break down or to involve the skin, insensitive to palpation, and quite painless apart from any discomfort which may be caused by the size of the mass. Deep glands may also be involved, and the spleen is always enlarged; sometimes it is as large as in chronic myelocytic leukaemia. The disease is compatible with good general health for a number of years but sooner or later more acute symptoms are wont to arise, with pyrexia, loss of flesh, marked anaemia, stomatitis, tonsillitis, diarrhoea and haemorrhages, though the last-named symptom is less common here than in myelocytic or in acute lymphatic leukaemia. The diagnosis is established, or rejected, by examination of the blood. A typical count in a patient first presenting himself for examination is: Red-cells 3.5×10^6 per cmm, haemoglobin 65 per cent, colour index 0.9, white cells 200,000 per cmm, of which 96 per cent or 192,000, are lymphocytes. The Jechman stained blood film shows a monotonous blue expanse of lymphocytes mostly of the small variety like those of normal blood in marked contrast to the variegated beauty of the well stained myelocytic film. Glandular enlargement is not a marked feature of myelocytic leukaemia; the nodes in the superficial zones may be just palpable but are not greatly swollen.

In lymphosarcoma the tendency is for the glandular groups to be unequally transformed into large masses; the individual nodes varying in size, insensitive, soft rather than hard, of limited mobility, and for the whole mass to be fixed to the deeper structures. The liability to deep gland involvement is great especially of the mediastinum, so much so that the first signs are usually either those of pleural effusion which may be bilateral and recurrent, or of intrathoracic pressure—for example dysphagia, cough, fullness of veins, recurrent laryngeal palsy or sympathetic paralysis. The patient is usually a young adult, and more ill in the early stages than in the corresponding phase of chronic leukaemia or lymphadenoma. The disease is often pyrexial; the diagnosis is confirmed by biopsy. A case of this sort which I saw with Dr. Gilbertson at Hitchin in 1923 is apparently unique in that the patient a young woman aged 20, has seemingly made a complete recovery.

Her story was that for five months she had had pyrexia which was irregular but seldom rose above 100°F . The right pleural cavity had already been aspirated on four or five occasions; the quantity of fluid removed varying from half to three and a half pints; the fluid was not blood stained and did not clot. Recently the left upper extremity had become swollen and the face was a little puffy; signs of effusion in the left pleural sac appeared and the subcutaneous veins on the left side of the abdomen became prominent. Enlarged glands which were painless sensitive firm and fixed were found in the left supraclavicular fossa. The patient was transferred to hospital where a biopsy proved the disease to be endothelial sarcoma and radiography showed

a large mass in the mediastinum. During the four months she spent in hospital fluid was withdrawn from the right side of the chest eleven times, and from the left seven times. Dr Finzi treated her with x rays, the mediastinal mass and cervical glands disappeared and she remains in good health five years afterwards.

Concerning lymphadenoma much has been recently written, and I would call special attention to articles by Rolleston, MacNalty, Fraenkel, Bennet and Ewing. The term "lymphadenoma," as at present ordinarily employed, probably does not indicate a single specific disease, but a variety of diseases more or less resembling one another in important clinical and pathological features, just as we now speak of the enteric group, which includes a number of fevers closely resembling one another in important features, but each one due to a specific bacillus, though formerly all were included in the term "typhoid fever."

The differential diagnosis of "lymphadenoma" on clinical grounds is often quite impossible, especially from tuberculosis (including endothelial tubercle) and from lymphosarcoma. But if the initial site of glandular enlargement is on one side of the neck, or, rarely, in the groin, if the whole group is affected, but not equally, the largest glands being towards the centre of the mass, if the area involved seems as though stuffed with glands, which are generally of equally firm consistency, discrete, and tending to remain so for a long time, relatively painless and insensitive, and with no indication of involvement of the skin or of abscess formation, the diagnosis is probably lymphadenoma. In lymphadenoma the liability to inclusion of all the superficial groups is relatively great, although there is much diversity in the rate at which this happens, there is a marked tendency for orderly spread of the enlargement from neck to axilla, and from axilla to groin, or vice versa. In the early stages the general condition of the patient is good, but, coincident with the spread of the glandular enlargement, a secondary anaemia is prone to develop, the patient becomes easily tired, is liable to sweats, pruritus, pigmentation of the skin (apart from that which may result from treatment by arsenic or by irradiation), loss of flesh, and pyrexia, which is sometimes of a relapsing character. Evidence of involvement of the intrathoracic glands, and, less often, of the abdominal groups, may be forthcoming, sometimes it is these nodes which are enlarged in the first instance. Lymphadenomatous tissue is prone to infiltrate other organs and tissues of the body, more especially the spleen and the liver, and the presence of palpable enlargement of the spleen is a valuable additional point in favour of the diagnosis. Lymphadenomatous deposits in the spleen arise both in the Malpighian corpuscles and in the pulp, the presence of these white deposits has caused the spleen to be called "hard bake" or "German sausage" spleen, and the recognition of these changes is of the utmost importance in confirming the diagnosis at the necropsy. Similar foci of infiltration are sometimes to be found elsewhere—in the pleura, in the lung, in the marrow, in the skin, and, most important of all from the clinical point of view, in the vertebrae, here they may cause pressure either upon the spinal cord with the production of paraplegia, or, by constriction of the intervertebral foramina, lead to severe "root pains" referred to the area of distribution of the corresponding spinal nerve.

The foregoing is an outline of a disease first described by Hodgkin in 1832, there are certain other features which are sufficiently common in the group to merit attention. The frequency with which some infection has occurred recently in the territory drained by those glands which are first affected is often a striking point in the history. A story of sore throat is by no means uncommon, and Sir Thomas Horder has told me of a case in which the axillary glands became the seat of lymphadenoma shortly after a septic infection of the finger. The tonsil is frequently the site of focal sepsis, and is regarded by many authorities as one of the portals of entry of the rheumatic virus and of the tubercle bacillus. It may possibly be the portal of entry also in those cases of Hodgkin's disease in which the cervical nodes are the first to be enlarged, yet it is very rarely that the lymphoid tissue of the tonsil, the thymus, or the Peyer's patches is involved in the disease. Though the enlargement of the nodes is usually slow and painless,

it may, on occasion, be rapid and painful, I have seen a case in which a mammary abscess was mimicked, and, at another time, sudden painful enlargement of glands in the right lower quadrant of the abdomen might easily have cost the patient her appendix. Exceptionally, one group of nodes only may be affected, and it is my firm belief that visceral infiltration may occur in the absence of demonstrable enlargement of lymphatic glands.

Of great interest is the relapsing pyrexia sometimes seen in this disease. In a monograph on the subject recently published by the Ministry of Health (see *Journal*, May 12th, p. 819) A. S. MacNalty states that

Lymphadenoma with relapsing pyrexia may be classified into two main types

1 A form in which the external lymphatic glands exhibit enlargement with or without enlargement of internal lymphatic glands

2 A form in which the internal lymphatic glands are alone affected

During the pyrexial periods the affected glands may become more swollen, the liver and spleen also, if involved, may increase in size, subsiding somewhat during the apyrexial interval. To quote MacNalty again

'In a typical case following on a period of low pyrexia or of normal or of subnormal temperature there is a steady rise occupying two to four days to a maximum of 102° 103° 104°, or even 105° F. For about three days the temperature remains at a high level, and then there is a gradual fall by lysis which usually occupies about three days also. The temperature then becomes subnormal, at any rate for a few hours. During the pyrexial period as a rule, the patient feels exceedingly ill, he has aching pains in the back and limbs together with chills, profuse sweats and loss of appetite. His expression is one of distress and anxiety.

The duration of either the pyrexial or the apyrexial periods is not constant, and they do not seem to bear any relation to one another.

Help in diagnosis is sometimes obtainable from the pathologist. Unfortunately, there is no blood picture characteristic of the disease—all that can be said is that a blood count showing an anaemia of the secondary sort, with no gross alteration in the absolute and differential leucocyte count, is not incompatible with lymphadenoma. The intradermal tuberculin test is negative save in those cases, by no means rare, in which tuberculosis and lymphadenoma coexist. There is as yet no serological test to help us. Even after the histological examination of a suitable gland—that is, one in which the disease process is still active—removed during life the diagnosis may be largely a matter of individual opinion, there is the typical variety which shows the characteristic histological features described by Sir Frederick Andrewes, and which all will admit as Hodgkin's disease, but in other varieties, which do not conform to this, the histologist who makes the diagnosis may make a lucky shot or be merely bluffing.

So also with regard to etiology there are many guesses, many suspicions, much perplexity. Lymphadenoma is probably an infection, and a stronger case has been made out against the tubercle bacillus than against any other known microbe, the indictment being that under unknown conditions the tubercle bacillus is able to produce these changes in some tissues and organs especially in lymphoid tissue, which differ from those of true tuberculosis.

So the disease, at present, is a mystery. Even the nomenclature is not settled, it answers in various quarters to Hodgkin's disease, to lymphadenoma, to lymphogranuloma, or to lymphomatosis granulosa.

Clearly, then, lymphadenoma is a condition calling urgently for research. At St. Bartholomew's a special fund, the Rose Research Fund, has been received for the investigation of lymphadenoma, clinical and pathological workers are co-operating in a special endeavour to elucidate it further. A team is in being, and a certain amount of progress has been made. Material is as yet scanty, and the fund will not be available for an indefinite period. We therefore invite practitioners to help us to "plug out the heart of my mystery" by sending any patients with enlarged glands of doubtful or uncertain nature for investigation. Sir Thomas Horder and I will readily take them into the hospital, and, if required, we have the surgical collaboration of Professor Gask.

THE THERAPEUTIC VALUE OF NEPHROPEXY*

BY

WILLIAM BILLINGTON, M.S.I.O.N., CH. M. BIRM.,
F.R.C.S.PROFESSOR OF SURGERY, UNIVERSITY OF BIRMINGHAM; SURGEON,
QUEEN'S HOSPITAL, BIRMINGHAM

TWENTY years ago this session I read a paper before this society entitled "The indications for nephropexy," a paper which was subsequently published in the *British Medical Journal*. At that time the subject was a very live one in Birmingham, the meeting was largely attended, and very strong views were expressed both for and against the operation. The question cannot even now be regarded as settled, and the object of this paper is to present as fairly as possible the results of my personal experience of nephropexy and its surgical treatment, in the hope that it may assist in arriving at a true solution.

Time does not allow of my dealing with many points of great interest and importance in connexion with the causes, pathology, and symptoms of nephropexy, nor can I enter into the methods I have employed in the selection of cases likely to benefit by operation. I intend to consider results only, and from them endeavour to show what therapeutic value has attached to nephropexy.

The results of nephropexy have to be considered from two aspects: (1) the surgical success of the operation in permanently replacing the kidneys in their normal position without unsatisfactory sequelae, such as pain in the loin or back, hernia of the wound, and persistent sinus, and (2) its therapeutic value in curing or ameliorating the symptoms for which it is performed.

SURGICAL RESULTS

At first these were very unsatisfactory. In a large percentage of cases the operation failed to cure the abnormal mobility of the kidneys, and they were found loose again almost as soon as active life was resumed. Many operations fixed the kidney to the muscles of the back and at too low a level, with the result that pain in the back was common and sometimes hydronephrosis developed. The use of silk and other non-absorbable suture materials was followed by persistent sinuses, and extensive damage to the muscles of the loin led to a feeling of weakness and hernia.

A further and very common cause of failure is the incomplete character of the operation. One kidney only is replaced, while the other kidney, which may also be mobile, and a possibly diseased appendix are left untreated. Satisfactory therapeutic results cannot be expected unless the operation, as such, is successful. Only when the surgeon is satisfied that both kidneys are in a normal position, and that possible associated or secondary abdominal lesions have been excluded or treated, can success be claimed.

The operation which I have performed upon upwards of 1,500 patients has been carried out in this spirit. My object has been to replace both kidneys, if both are loose, and to make sure that no intra-abdominal lesion is left undetected and untreated.

The surgical results have been very satisfactory. In no single instance have I found a kidney loose again, although on a number of occasions I have reopened the loin, thinking that it had become so. The usual cause of error is a Reid's lobe of the liver, and on the left side a prolapsed spleen, conditions which may simulate a movable kidney very closely. In my earlier cases before I opened the peritoneum as a routine, an enlarged gall-bladder on several occasions was mistaken for a kidney which was thought to have broken loose after replacement. In no case has there been a persistent sinus, and no second operation on this account has been needed. In some twenty cases I have had to excise a length of the last dorsal nerve subsequently on account of pain caused by its implication in scar tissue and a few cases have been operated upon for hernia of the scar. Very occasionally, where at the time of operation a moderate hydronephrosis existed this has increased and necessitated excision of the kidney. My experience has been that where the pelvis of

the kidney is sufficiently dilated to hold more than about two ounces of urine replacement fails to prevent its destruction by hydronephrosis, while if the pelvis is dilated to a less extent the operation succeeds in doing so.

The results in my large series of cases extending over twenty-five years have been such as to justify the claim that movable kidneys can be treated successfully by operation, and that the operation is safe and comparatively easy. It is essentially a plastic operation, and if therapeutic results justify it there are no surgical reasons why it should not be done.

THERAPEUTIC RESULTS

Very widely differing views are held as to the importance of movable kidney as a cause of chronic ill health, and of the value of nephropexy as a therapeutic measure. In the early years of the present century extravagant claims were made that nephropexy was responsible for a vast amount of functional disturbance of mind and body, and it was asserted that the kidneys should be fixed in such cases whenever any undue mobility was detected. The results of this were unfortunate, as they always are whenever the usual care in selection of cases is abandoned and a new treatment is applied indiscriminately. The claims that Koch's tuberculin is a cure for phthisis, that hunger pain in association with hyperchlorhydria indicates duodenal ulcer and calls for gastro-enterostomy, that the teeth are responsible for most cases of rheumatism and should be sacrificed wholesale, and that movable kidneys are the cause of much functional nerve disturbance and should be treated whenever found in association with it, have all led to disappointment when extensively acted upon. Medicine is much less simple than this, and a claim that a panacea has been discovered for any common disease or clinical syndrome generally brings disappointment when blindly accepted.

The wide and indiscriminate operating for movable kidney was attended by unsatisfactory results and caused the pendulum to swing in the opposite direction, with the result that it is often asserted that nephropexy is rarely of importance and still more rarely calls for treatment. The truth lies somewhere between these two extremes. Unquestionably, anyone who has carefully studied the problem, and has brought to bear upon it the same care and judgement in the selection of cases suitable for operation, has paid the same attention to technique, and has followed up the operation by necessary after-treatment as for other surgical conditions, cannot fail to be convinced that nephropexy may be a cause of lowered efficiency and chronic ill health, and that treatment of it by nephropexy may be called for.

Great care must be exercised in deciding the suitability or not of a particular case for nephropexy. The necessity for a satisfactory technique and a complete operation has been emphasized. It is, also, all-important to remember that time and suitable after-treatment are needed to complete the cure. So many operations are followed by immediate and dramatic benefit that disappointment is often caused to surgeon and patient when an interval of six months or a year must elapse between the operation and its beneficial result. No patient can emerge from a state of severe and long-standing neurasthenia in a short time, even though the cause has been removed. This is the reason why so many patients operated on for movable kidney recover slowly from the symptoms from which they were suffering at the time of operation. I never assess results until a full year has elapsed from the operation, and even this length of time is often insufficient, and only after two or three years is full health obtained. Two facts stand out in connexion with my results: (1) that the failures have never improved to any extent after operation, and (2) whatever benefit is obtained is retained, relapse is almost unknown. Also the investigation into results is carried the better they are. If only it became sufficiently realized that in a large proportion of cases the effect of nephropexy is to convert an incurable condition into a curable one, and not of itself to establish a cure, the percentage of failures would diminish and the true value of the operation be better understood.

I would most emphatically state that no moral value whatever attaches to the operation. In my opinion the

*Valedictory presidential address to the Midland Medical Society.

moral effect on the patient is wholly bad, and there is not one redeeming feature. From the moment operation is mentioned until it has been completely recovered from and forgotten the effect is to put a further strain upon a mind and body already over-stimulated and exhausted. The whole question of operation is fraught with greater responsibility than usual, and unless it is felt that the benefit likely to result justifies it, nephropexy should not be done. It is advisable to draw particular attention to this point because I have often heard it asserted that the benefit that follows nephropexy is due to the moral effect of the operation upon the patient, and I have frequently been requested to perform it for that purpose. On one occasion I saw a man who had had an incision made into the loin to impress him that his kidney, which he had been told was loose, had been put right. Such procedures are entirely wrong. It is questionable whether the mental and physical injury caused by an operation ever confers any benefit except in so far as it remedies a physical trouble, and the harmful effects of operations, as such, are considerably greater in neurasthenic patients. It is therefore reasonable to assume that any benefit following nephropexy is due, not to the fact that an operation was done, but to the replacement of the kidneys that it effected.

RESULTS OF NEPHROPEXY IN MY OWN SERIES OF CASES

My personal experience of nephropexy extends, as I have said, over twenty-five years, and during that time I have operated upon more than 1,500 patients and replaced more than 2,000 kidneys, the double operation having been performed in the majority of cases. All my patients have been referred to me by practitioners, and it is their encouragement and support which has made me feel that the operation has justified itself. After all, in my opinion, it is the patient's own doctor rather than the surgeon who ultimately determines the value of any form of treatment. He has an intimate knowledge of his patient that no specialist can acquire, it is a knowledge based upon prolonged observation of the patient himself and his reactions to and upon those who come in contact with him. Where nervous and functional disturbance are predominant features improvement is often more evident to the family doctor and the patient's relatives and friends than to the patient himself, and the doctor's verdict is perhaps the best test of value that can be obtained. On this verdict, rather than upon such tests as I have been able personally to apply, I have been content to rely. No more graphic description of the effect of the operation could be given than that volunteered by the husband of one of my patients—that "before the operation my home was a hell, and now it is a heaven."

It is very difficult to obtain accurate statistical evidence of the therapeutic benefit conferred by nephropexy. Some years ago I made two different investigations. For the purpose of the first I wrote to 100 consecutive patients in my series, one full year having elapsed in every case between the operation and the inquiry. I was successful in obtaining information about 87 of these patients, and from that I ascertained that about 60 per cent were well in the sense that they were leading ordinary lives and did not need medical attendance, 20 per cent were considerably better, 10 per cent were better, and 10 per cent were no better.

The second inquiry took the form of a questionnaire addressed to eleven practitioners, 70 of whose patients I had operated upon. The questions submitted to them were: In the case of (1) Has the operation been a surgical success—that is, has it efficiently and permanently anchored the kidneys, and has it been free from unpleasant sequelae? (2) Has the general resulting benefit justified the operation?

Great care was exercised by the doctors to make the answers reliable, and each patient was either written to or personally interviewed. The actual replies were printed and circulated among the members at a meeting of the Surgical Section of the Royal Society of Medicine on January 13th, 1914. They indicated in all the 70 cases that the operation was a surgical success in one case only, that of a lady who complained of pain in her right side—was there any mention of after-trouble. Of the general

benefit that resulted, only 5 were reported as failures, while many were described as having been changed from chronic invalids into absolutely normal people.

These satisfactory results do not appear to have been obtained by the majority of other surgeons, and the tendency is for fewer and fewer cases of nephropexy to be operated upon. This led me to make a still further and more drastic investigation into my results. All the patients upon whom I had operated during the five years 1922-26 were written to and invited to answer the following questions:

1. Have the operation wounds troubled you? If so, in what way?
2. Have the symptoms for which the operation was performed been cured?
3. What is your present state of health?

Of the 213 patients written to replies were received from 163. It soon became evident from the replies that the answers to the first two questions were of little value, and that the answers to the third supplied the true test.

All these patients suffered from symptoms sufficiently severe to call for medical attendance, and had proved incurable by ordinary methods of treatment. The symptoms complained of were very variable, but in every case the renal mobility was held to be the principal cause. In every case the operation was a complete one—that is, both kidneys were fixed when both were loose, and an abdominal exploration from the loin was carried out. In nearly all the appendix was removed.

In order to obtain an independent and absolutely unbiased report the replies were submitted without comment to Professor Kauffmann, whose wide experience of both private and hospital patients peculiarly fits him to estimate their meaning. I am very much indebted to Professor Kauffmann for the great interest he has taken in this investigation, and I am convinced that his report will receive the consideration it deserves. It estimates, as impartially as is possible, the true results of the operative treatment of nephropexy.

Professor Kauffmann's Report

"The replies from 163 patients have been carefully considered with a view to my forming a conclusion as to the results of the operation for nephropexy. I have, of course, only the patients' replies from which to judge, and a certain difficulty is introduced by the second question, inasmuch as many of them scarcely know or remember the groups of symptoms for which they sought advice. Guided by the kind of reply, and to some extent by the tone of the reply, I have divided these 163 cases into five groups—namely:

- | | |
|---|----|
| 1. Complete success, where the statement warrants the name | 23 |
| 2. Success | 42 |
| 3. Partial success, where the benefit outweighs any remaining troubles | 41 |
| 4. Partial failure, where the remaining troubles outweigh such benefit as the patient has derived | 22 |
| 5. Failure | 25 |

"I have not felt able to make allowances for such things as gravidity or possibly some new trouble coming on, as it must do in some proportion of the cases in an interval of several years. It is more than likely that some cases which would have been in one of the successful groups have been spoilt by new disease thus intervening.

It seems, therefore, that, taking complete success and success together, these groups account for 43.6 per cent partial success—accounts for 25 per cent, failure for 17.7 per cent, and partial failure for 13.5 per cent. These figures are, I conclude, very satisfactory.

By far the greater number which constitute groups 1 and 2 together have had appendicectomy as well as kidney fixation, generally double. But success is also found in those who only had a kidney fixation, single or double, done.

I have considered the question whether the addition of appendicectomy, or other operation, has affected the results, but can get no satisfactory answer, since, in the successful group, nephropexies without other operation only formed 12.6 per cent, and in the partial failure and failure groups 13.7 per cent."

Commenting upon Professor Kauffmann's report, I would draw attention to the severity of the test applied. Results are mainly determined by the answer to the question "What is your present state of health?" Only those cases in which the answer indicates that the general health is satisfactory in every way have been placed in the

successful group. Patients who state that although relieved of the symptoms for which the operation was done they do not enjoy normal health owing to other troubles are labelled partial successes or failures according to whether their general health and working efficiency appear to have been improved or not. The disappearance of one set of symptoms and the substitution of another set in their place with the result that comfort and working efficiency have not been materially improved is regarded as evidence of failure. Further, as Dr Kauffmann points out, no allowance has been made for the entirely new troubles which may reasonably be expected to develop in a certain number of cases over an interval of several years. The report therefore, may be taken as indicating in a conservative way the proportionate effect of the operation in raising to a normal standard of health patients who were in a state of chronic invalidism.

The following may be said to summarize the results of Professor Kauffmann's investigation of 163 cases, operated upon at intervals of from six and a half to one and a half years prior to the inquiry (13 of these patients were men and 150 were women)

Successful	71=43.6 per cent
Partially successful	41=25.0
Failures	51=31.4

A BEDSTEAD FOR USE IN TREATING CARDIAC PATIENTS SUFFERING FROM CONGESTIVE FAILURE

BY

SIR THOMAS LEWIS, M.D., F.R.C.P.,*
PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL

For many years the need of a bedstead specially constructed to suit cardiac patients suffering from congestive failure has been felt. Such patients are usually orthopaedic and require propping up with bed-rests or a pile of pillows,

FIG 1

from these they are apt to slip down at night, an accident usually occasioning distress and loss of sleep and sometimes avoided by the rather clumsy device of tying a bolster across the bed below the buttocks. Some of the patients are oedematous, and drainage into the legs from the trunk, or from the legs by tubes or incisions, is required sooner or later. Drainage necessitates the sitting posture, and the patient must be moved into and nursed in a chair. Many of the patients are restless unless frequent changes of posture are allowed them, many prefer to sleep in a chair rather than in a bed at night.

To nurse patients suffering from congestive failure often means very heavy work, and unless special devices are used, these patients are apt to exert themselves much more than is good for them. It is sound to insist that patients of the class considered should make no muscular effort that

Working on behalf of the Medical Research Council

These results, taking into consideration the kind of patients operated upon, though by no means justifying a claim that nephropexy is a panacea for neurasthenia and functional disturbance when complicated by renal mobility, are satisfactory. The patients had all undergone prolonged treatment, and were referred to me because of their failure to benefit by it. They were the neurotic sloth and jetsam who are the despair of their friends and medical attendants. Nearly all were in early adult life with many years of activity in front of them. Most of them were under the necessity of earning a livelihood or managing a household, and the change from chronic invalidism and inefficiency to normal health and efficiency that has been effected in nearly half of them would seem to justify the performance of an operation which is almost free from risk and which is essentially plastic in character.

Looking back over the long series of cases of nephropexy that have come under my observation, in only about one-third of which I have operated I cannot help feeling that the results would have been better had the condition been effectively treated at an earlier stage. In no branch of surgery can the best results be expected in the later stages of disease and in the medical failures, and nephropexy is no exception to the general rule.

can reasonably be avoided, they should be supported constantly, and should never support themselves. They should never move themselves, or put forward effort in assisting a nurse to move them. Experience shows that under such a regime improvement is more likely or is more rapid than under a less rigid system of treatment.

Very many of the difficulties of nursing otherwise encountered are overcome by using a bedstead that has been built for me by Messrs Whitfield's Bedsteads, Ltd., of 10, Dane Street, High Holborn W.C.1. This bedstead can be used completely flat or can be converted within a minute or two into a chair, as shown in the illustration. The back-rest *a* is raised into the position shown, or to any other desired angle, by a detachable crank handle moving a quick-thread screw at the head of the bed. A second

FIG 2

and independent screw, also at the head of the bed, raises the thigh rest *b* to any desired position, this second rest prevents the patient from slipping downwards. Both these movements are executed quite smoothly, and the corresponding rests are at once stable at any angle to which they have been raised. The third movement, the lowering of the leg-rest *c* is accomplished by hand, the leg-rest being adjusted at any desired angle on two strongly toothed rials, which drop upon a stiff steel bar. The foot-rest *d* is adjustable on the leg rest to suit legs of different lengths.

The bed has four legs on the main rigid frame, and two additional legs *c*, carried on the end of the leg rest and falling under the bed when the leg-rest is dropped. The additional legs were not included in the original design, but have since been added to support, not the patient, but the occasional visitor or student who throws his weight on to the end of the bed. The mattress is made in three

pieces to fit the three parts of the bed the three pieces being hinged together. The bed has been in use in my wards for two years, and is much favoured by both patients and nurses. Patients can be moved frequently and without effort, they are more comfortable and are more completely rested than formerly.

The original model of this bedstead was built with funds generously given for the purpose by Frederick Faust, Esq.

THE ACUTE PELVIS *

BY

EDWARD WILLIAMS, M.D., M.R.C.P.,

Assistant Obstetric Physician, Charing Cross Hospital

THE object of the present short communication is to bring forward some points of interest in the diagnosis and treatment of cases presenting symptoms suggesting acute pelvic conditions. The observations are based on cases in my own experience. They may be conveniently grouped into those presenting symptoms accompanied by fever and those which present symptoms accompanied by shock. The symptoms may be associated with bilateral signs in the pelvis or by signs localized to one or other side.

Symptoms suggesting Acute Pelvic Lesions accompanied by Fever

When a bilateral tumour or marked tenderness, situated at both sides of the uterus, is discovered in a woman of the child-bearing age the diagnosis of a pyosalpinx or acute salpingitis is suggested. The interest of the condition lies more in the matter of treatment than diagnosis, and centres round the time of election for operation. Comparison between the pathology of acute salpingitis and that of puerperal peritonitis illustrates the value of delaying operation until the inflammatory process has become well established.

In the very fatal peritonitis following labour or miscarriage the abdomen is found at laparotomy more or less filled with purulent discharge, and pus is seen issuing freely from the open mouths of the abdominal funiculi. This suggests that salpingitis and pyosalpinx formation is a protective mechanism, and that it is in part the reaction in the Fallopian tube which prevents every ascending infection from becoming generalized. If this is granted it affords the indication for surgical intervention during the acute stage of salpingitis—that is, when there is evidence that the limiting process has failed and the disease is spreading, or when there is uncertainty as to the diagnosis. It may be true that surgery in the early stages will accelerate the convalescence, but the recuperative powers of the Fallopian tube are too well known further to remark upon, and the value of conservatism is nowhere better seen in gynaecology than in the treatment of disease of this structure.

Bilateral tenderness in the pelvis, apart from definite tumour formation, is included because of the occurrence of acute pneumococcal peritonitis, which may be found in adults in the primary form and may simulate an attack of salpingitis. It is mentioned because the symptoms in the earliest stages may be referred to the pelvis rather than to the general abdominal cavity. When the signs are unilateral the difficulties of diagnosis are greater. If the symptoms are accompanied by signs on the right side of the pelvis, the main point in the differential diagnosis will be to distinguish between appendicitis and salpingitis, in view of the divergence in the treatment of the two conditions. Either of them may present such a variable picture that a diagnosis based upon the inflammatory phenomena as they affect these two neighbouring viscera is bound to fail quite frequently.

In contradistinction to appendicitis, salpingitis is the last stage in a morbid process, and if attention is focused on the whole of the genital tract, the evidence of this will generally be found by the presence of signs of inflammation in the lower part of the tract.

Although less common more interest attaches to cases with left-sided physical signs, owing to the fact that diverticulitis, with peridiverticulitis, frequently gives rise to signs and symptoms suggesting a lesion of the left tube or ovary. While the condition may occur during the child-bearing period, it is more usually a post-climacteric disease.

Inflammation is the commonest pathological change around the sac, and the accompanying inflammatory oedema and hyperplastic inflammation in the bowel wall lead to the formation of a definite tumour, while the formation of adhesions to the pelvic viscera adds to the difficulty in differential diagnosis. The development of a pyosalpinx after the climacteric, on the other hand, is very unusual, as the records of the gynaecological department of Charing Cross Hospital show.

The x-ray appearances after a barium enema are of considerable diagnostic aid, and further serve to distinguish the condition from malignant disease of the bowel, with acute symptoms superadded.

The treatment of these cases of diverticulitis is of very considerable interest, but space does not allow of its inclusion.

Symptoms suggesting Acute Pelvic Lesions accompanied by Shock

In women of the child-bearing age the complications of ectopic pregnancy come first to mind, and seldom present difficulties in diagnosis or management. Some new diagnostic tests have been described within the last few years, but they do not materially aid in diagnosis.

One of these is called the phloridzin test. A positive reaction depends upon the production of glycosuria following the injection of phloridzin, and indicates only the condition of pregnancy. I have no personal experience of it, and two factors materially reduce its value in acute conditions. First, considerable time and the facilities of a laboratory are necessary for its performance. Secondly, after rupture and the formation of a haematocolo the test becomes negative, according to some observers, even if previously positive.

Another is the "shoulder pain" test. Rubin has called attention to the occurrence of the same sign when gas enters the peritoneal cavity in the course of a tubal insufflation. It depends presumably on the presence of some irritating foreign substance, such as blood, in the upper part of the peritoneal cavity. It is an unreliable sign. While it may be found with ruptured ectopic pregnancy, yet the abdominal cavity may contain much blood and the sign be absent.

Cullen has described a sign which is known by his name, and, if found, is considered to be pathognomonic of a ruptured ectopic pregnancy. It consists of a bluish discoloration of the skin around the umbilicus, and has been noted from time to time by different observers. It is a sign which is only occasionally present, and I have not myself ever observed it.

The subject of the treatment of the gravid tube, whether by salpingectomy or by the more conservative salpingostomy, must still be considered an open question. It will presumably remain so until the etiology of ectopic gestation is known. In this connexion the increasing number of cases of repeated ectopic pregnancy reported in the literature is interesting.

The rare condition of haemorrhage into the ovarian tissue and the formation of a pelvic haematocoele, which may accompany delay in ovulation, is only of academic interest. The etiology is unknown, and the differential diagnosis from ectopic pregnancy cannot be made prior to operation so far as I am aware.

A difficult differential diagnosis is presented when symptoms occur suggesting torsion of the pedicle of an ovarian cyst. It is well known that patients with an ovarian cyst may develop acute symptoms due to some other intra-abdominal or pelvic condition, and I recall three cases which well illustrate the point. In one of these the acute symptoms were due to acute haemorrhagic pancreatitis, in another they were due to volvulus of a portion of small intestine during early pregnancy, and in the third to acute appendicitis.

My experience leads me to believe that the importance of the urgent symptoms attending torsion of the pedicle

of a cyst is exaggerated. These symptoms are usually described as the onset of sudden abdominal pain, together with vomiting or other alimentary disturbances. On examination some degree of shock is found and muscular rigidity of the abdominal wall.

Analysis of the cases of actual or supposed torsion of the pedicle of a cyst which I have seen leads to the conclusion that the more urgent the symptoms of internal strangulation the less probably is the case one of a strangulated cyst but more probably of some other intra-abdominal catastrophe, accompanied by the presence of an ovarian cyst.

The explanation offered that when at laparotomy a cyst is found which had undergone torsion the occurrence of the twist was gradual rather than sudden in onset is, in the absence of any clinical signs suggesting it, equally difficult of proof or disproof. It must remain an open

question until more is known concerning the mechanism of the torsion, which is certainly very obscure.

In conclusion, I wish to draw attention to two points only, which have impressed themselves upon me, and they are these: (1) the need for a thorough examination of the whole abdomen and pelvis in the matter of diagnosis, and (2) in treatment such an operative exposure as will allow of a thorough exploration of all the organs that may be diseased. In hospital out-patients we quite frequently see women with a small incision in the right iliac fossa through which an appendicectomy has been performed, still presenting a pelvic syndrome, and requiring a further operation on their pelvic organs. These "button-hole" incisions do not offer suitable exposure for the surgery of the female pelvic organs, and their use may be discontinued with advantage.

A CASE OF COMPLETE GASTRECTOMY FOR CARCINOMA OF THE STOMACH

BY

D. R. FLINT M.B., Ch.B., F.R.C.S.

ASSISTANT SURGEON, GENERAL INFIRMARY, LEEDS.

(With Special Plate)

The patient whose case is here recorded is a labourer, aged 44, who was under the care of Dr. Broughton of Batley, he was admitted to the Batley Hospital on May 24th, 1927. His complaint was painful indigestion, with loss of weight and appetite. He had been in good health up to two and a half years before, when the indigestion started. The pain came on within half an hour of taking ordinary food, was felt in the epigastrium, and gradually passed off before the next meal. At first the pain was relieved by lying down, and sometimes by pressure over the pit of the stomach. The attacks lasted some three or four weeks, and were followed by periods of several weeks of almost complete freedom from symptoms. During the attacks flatulence was a very troublesome feature, and in attempts to relieve himself of this by belching small risings of food occurred into his mouth, apart from this there was never any vomiting of food or blood, and no melaena had been noticed. The bowels were rather constipated. The last attack began in December, 1926, and was continuous up to the time of operation, it was during this period that his appetite failed and the main loss of weight occurred. He had lost about 1½ st during this time.

On admission to hospital the patient was in fairly good condition but anemic and rather flabby. His weight was 8 st. Abdominal examination showed the abdomen to be thin and rather hollowed, and though there was nothing definitely abnormal on palpation, there was a suspicion of an ill-defined lump in the epigastrium. A diagnosis of carcinoma of the stomach was made, and it was thought it might have become implanted on a chronic gastric ulcer. Operation was advised and was performed on May 26th, 1927. The usual right paramedian incision was made, and a growth was found occupying the greater part of the stomach, which was small, thick, and nodular. There were thin adhesions to the pancreas, and several glands were noted along the lesser curvature, especially close to the oesophagus at the origin of the gastric artery. No secondary deposits could be felt in the liver or pelvis. It was quite obvious that nothing could be done to rid this man of his disease other than a complete gastrectomy, and I decided that it was worth while giving him his chance.

The pyloric artery was ligatured and two Parr's clamps applied to the first part of the duodenum. The duodenum was divided between the clamps and the two cut ends cauterized by heat, and the distal one infolded over the clamp, thus was slipped out, the suture tightened, and then infolded by a second line of stitching. The gastro-colic omentum was divided along the whole length of the

stomach about 2 in. from it, and the lesser curvature was similarly treated, the gastric artery being ligatured at its origin from the coeliac axis, thus enabled me to remove the last palpable gland. Fortunately there were very few of the pancreatic glands involved. The whole stomach could now be lifted up, giving a very clear view of the lower end of the oesophagus. A clamp was applied across the cardiac orifice of the stomach, and by using this as a retractor enough oesophagus could be drawn down to enable me to suture it with reasonable ease to the jejunum. The jejunum was drawn up in front of the transverse colon so that there was no loop left between the part selected for suture and the duodeno-jejunal flexure. The stitching was carried out in the same way as for gastro-enterostomy without clamps, the stomach being cut away little by little as the sutures were inserted. By using the stomach as a retractor until the suturing was practically finished no great difficulty was encountered in uniting the jejunum to the oesophagus.

The patient bore the operation well, and on returning to bed was put on to continuous rectal saline at once. He began sipping small quantities of water at the end of twenty-four hours, and the quantities were gradually increased with the addition of milk and tea, until at the end of ten days he was taking as much as he asked for. Solid food was begun in a fortnight, and steadily increased. He was up within a month, and eating ordinary food in small quantities and often. Although he had lost all desire for food before operation he was now thoroughly enjoying his meals, but had to take them slowly, otherwise he felt a sensation of distension, and almost as soon as he had finished one meal he was feeling hungry again. This is rather a curious occurrence, for we are led to believe that the sensation of hunger is due to gastric contractions.

I had this man treated subsequently with deep x rays, but I am unable to say whether it did him any good or not. He had a kind of hemicolon diarrhoea for some months after operation, which gradually disappeared. The man is now (October, 1928) back at work, eating well, enjoying his food, feeling well, and apart from a little anaemia has a normal healthy appearance.

The pathological report on the excised stomach was kindly made for me by Dr. M. J. Stewart, and is as follows:

"The specimen received consists of the entire stomach with about 1 in. of the duodenum. The pyloric three-fifths of the organ is largely occupied by a deeply cratered, ulcerated carcinoma, measuring 4½ by 4 in. in its two chief diameters. The centre of the lesion is on the posterior wall 2½ in. from the pylorus and exactly midway between the lesser and greater curvatures. The growth has extended across both curvatures so as to encircle the organ only an inch or so on the middle of the anterior wall escaping. The lower margin of the tumour extends to within 3/4 in. of the pylorus. The appearances suggest a primary carcinoma with secondary ulceration. The margins are much thickened, undermined and overhanging, and the contour while generally circular is very irregular. The floor everywhere obviously composed of growth, is irregularly nodular and ulcerated. Externally there are extensive dense adhesions in the lesser sac between the stomach in the region of the growth and the pancreas and retroperitoneal adipose tissue. Pale masses of growth can be seen beneath the serosa but there is no

evidence of actual peritoneal invasion. Several glands along the lesser curvature are slightly enlarged.

Histologically the tumour is a carcinoma of great cellularity. In general the structure is epithelioid-celled ('encephaloid cancer'), but there is occasional acinar formation, and in places there is an abundant fibrous stroma. The tumour tissue has completely penetrated the muscular coat over large areas but nowhere is there a cancer-cell free sclerotic mass indicative of pre-existing simple ulceration. Many nerve fibres are embedded in the surface layers of the growth subserosally, where there are also some touch-corpuscles in close relation to it. Three lymph glands examined microscopically show extensive invasion.

On November 1st, 1927, I admitted this man to the Leeds General Infirmary for investigation, as I was curious to find out, if I could, how he had compensated for the complete absence of his stomach. At this time he had gained about 1 st in weight, was feeling fit, and eating ordinary food, though slowly and in small quantities. If he ate hurriedly or large amounts he felt distended and uncomfortable, however, he soon became hungry again. He had a craving for sugar and salt.

FIG. 1.—Showing the extent of the growth after laying open the stomach.

The following results were obtained from various investigations, and I wish to express my thanks to Dr. Scorgill, radiologist at the Leeds General Infirmary, and to Dr. Fownes and Dr. Hartnell, pathologists at the same institution, for their valuable help in this respect.

X-ray Report November 3rd, 1927

- 1 A solid cachet was given. This passed straight into the jejunum, no delay at the anastomosis.
- 2 Fluid meal. This floods the upper small intestine at once, none is seen to pass backwards into the duodenum.
- 3 Four hours after giving the barium meal all the barium is in the lower ileum.
- 4 Six hours after giving the barium meal caecum filled some still in the lower ileum (normal findings).

Blood Examination November 2nd 1927

The blood count showed red cells 4,500,000 per c.mm., leucocytes 2,900 per c.mm., haemoglobin 76 per cent., colour index 0.84. Film. The red cells show slight variation in size and shape but they stain well and evenly. The leucocytes show nothing for special comment beyond leucopenia. Differential count. Eosinophil polymorphs 1 per cent., neutrophils 59.5 per cent., large mononuclears 5 per cent., lymphocytes 34.5 per cent. Blood sugar 0.11 per cent. (normal 0.08 to 0.12 per cent.) Blood cholesterol 15 per cent. Urea nitrogen 19.6 mg. per 100 c.cm. blood (normal 10 to 20 mg.) CO₂ combining power 57.5 c.cm. of CO₂ bound as bicarbonate by 100 c.cm. of plasma (normal 60 to 70 c.cm.)

The saliva on November 2nd 1927, showed alkalinity equivalent to 0.03 per cent. sodium carbonate (normal 0.08 to 0.1 per cent.).

On November 8th an eighteen hour culture of faeces showed growth of *B. coli*, no pathogenic organisms were isolated bile salts present. Total solid matter 40.7 per cent. of dried faeces, containing fatty acids as soaps 17.3 per cent., free fatty acids 16.5 per cent., neutral fats 7.1 per cent. of dry faeces. The faeces contained 17.07 per cent. of dry matter. Fat-splitting appears normal but there is some deficiency in absorption of the split fat. Microscopic examination showed some undigested muscle fibres present, apparently in greater number than usual. Undigested vegetable material was also present. The urine on the same date was normal.

An attempt was made to recover some of the contents of the jejunum after giving a test meal on the lines of the usual gastric test meal, it was found impossible to get sufficient for examination, I assume because of the rapid passage onward of the food.

I think this case is worthy of publication as the number of cases of successful complete gastrectomy for carcinoma of the stomach is very small. It is remarkable how efficient has been the compensation for total absence of the stomach. Six months after operation, apart from slight anaemia and leucopenia and a little deficiency in fat-splitting, there seems to be no noticeable alteration in the functions of his various systems so far as these can be determined. Possibly the fact that he consumed large quantities of dilute hydrochloric acid at and between meals is partly responsible. It was found impossible to get him to continue this after he had returned to work.

It is now about eighteen months since the operation, and he is apparently quite fit and able to do reasonably hard work, and enjoys his food. He is free from anything which would suggest recurrence, and shows no sign of anaemia, though a blood examination has not been made since last November.

CYSTICERCOSIS OF THE BRAIN:

WITH REPORT OF A CASE

BY

W. BROUGHTON-ALCOCK, M.B. Cantab,
D.C.M.S. (Path.), MINISTER OF PENSIONS

W. E. STEVENSON, M.B., B.S. Durm.,
MEDICAL SUPERINTENDENT, MINISTRY OF PENSIONS HOSPITAL, MAGHULL;

AND

C. WORSTER-DROUGHT, M.A., M.D. Cantab., M.R.C.P.,
PHYSICIAN WEST END HOSPITAL FOR DISEASES OF THE NERVOUS
SYSTEM AND METROPOLITAN HOSPITAL AND NEUROLOGIST
MINISTRY OF PENSIONS

(With Special Plate)

Cysticercus cellulosae is rarely met with in this country, and, so far as we can ascertain, the following case is the only one for many years that has come to necropsy in England.

Description of Case

History.—The patient enlisted in the army in June 1918 at the age of 18 and proceeded to India in 1919. In July 1921, he developed enteric fever, which was complicated by thrombosis of the right leg. In June 1922, the vision of his left eye became rapidly impaired (vision 6/60) and a report states "atrophy of the retina due to retinitis", but it is admitted in a note made in the following month (July) that the diagnosis at present is not definite. Later the eye condition appears to have been attributed to an embolus of the retinal artery, but a further report in October, 1923 states "left vitreous occupied by mass of vascularized fibrous tissue". Eventually the eye was enucleated at the Royal London Ophthalmic Hospital on July 26th, 1924. Dr. H. Coverdale from the records of this hospital, kindly informs us that the left eye showed chorioretinitis, old keratitis punctata posterior synechiae and cataract with no perception of light. The right eye was normal. Unfortunately the pathological notes are missing. In view of his subsequent history however, it is practically certain that the eye was affected by cysticercosis. In April 1923 his first epileptic fit occurred on the ship returning from India. The fits recurred from time to time at variable intervals, he would have as many as seven in twenty-four hours, but might be free for as long as six weeks, they were both diurnal and nocturnal.

Description of Fit.—A warning usually occurred with loss of power in either hand or in the right leg, unconsciousness followed and during the attack he frequently bit his tongue and passed urine. The fit was invariably followed by severe headache and occasionally by purpura of the right arm lasting up to half an hour. After a series of seven fits he once had complete loss of power in

B Upper edge of barium meal

the left arm and hand lasting three days with gradual recovery. Occasionally he would vomit within twenty-four hours of the fit. In November 1925 two definite attacks were witnessed by a resident physician in hospital. They were both Jacksonian in type affecting the right side of the face followed by a period of unconsciousness but no generalized convulsion. During the latter part of 1927 the fits became more frequent and his speech became affected.

Physical Signs (March 27th, 1928).—Cranial nerves. Right pupil sluggish to light, left eye absent. No nystagmus. Slight right-sided facial weakness. Speech of 'bubbar' type. No muscular weakness of limbs. Deep reflexes brisk but equal. Right plantar flexor left doubtful. No definite inco-ordination. Mentally he was very dull and able to give but little account of himself. During the next two weeks he complained continuously of headache vomited on one occasion became very lethargic and died suddenly on April 11th aged 28.

Pathological Description

The right half of the brain and a cyst attached to the dura mater were received for detailed examination.

On inspection of the cortex forty rounded white nodules in size from that of a lentil to that of a pea and lying both in sulci and in the middle of gyri are seen irregularly embedded in the cortex and in the greater number over the vertex of the hemisphere. On the mesial surface similar cysts are irregularly scattered but are less numerous than on the outer surface. There is no macroscopic evidence of pus or inflammatory reaction nor of softening in the brain substance surrounding the cysts and none of the cysts seen shows calcification. They are firm to the touch giving one an impression rather than a thought of tuberculo-sclerosis.

It may here be added that at necropsy cysts were visible on the dura of the vertex as soon as the skull cap was removed. The one sent with the brain is from among those found in the basal membranes. The left hemisphere was cut up examined and then thrown away. It is reported to have been similarly infected.

On section of the right cerebral hemisphere a few cysts are seen scattered about the cerebral substance and appear almost exclusively confined to the grey matter when present in white matter they are at the border of grey matter (Fig. 1). A few cysts occur in the mesial portion of the occipital and frontal lobes and in the basal ganglia there are relatively as many as in the cortex, they are present in both the lenticular nucleus and optic thalamus. In the pons on section a single cyst the size of a small pea is found lying nearer the ventral than the dorsal surface about two-thirds the distance from the superior limit of the pons to the medulla. None are seen in the medulla. As far as we can estimate the number of cysts in the half brain is about 100.

On the cortex of the cerebellum are three cysts each the size of a lentil while on section one cyst is seen deep in the substance of the organ.

No cyst in the cutaneous and muscular structures or other organs was detected at necropsy the spinal cord was not examined. In the old clinical note no mention is made of *Taenia solium* occurring in the intestines.

On section the cysts in the brain substance show the interior of the cystic envelope or adventitious membrane to be smooth and glistening, and to contain little if any clear fluid. Attached within this envelope at one site are much smaller clear brownish circular cysts varying in size and rounded or ovoid in shape, some appear as swollen grains of rice covered with a brownish membrane others that are larger are more balloon-like and contain more fluid, the invaginated scolex lying like a grain of rice within or partly within and partly without the balloon-like membrane or cysticercus outer wall (Fig. 2).

By direct examination typical characters of the scolex with its hooklets and four suckers are seen (Fig. 3). An interesting feature in two of the cysticerci examined microscopically is the presence of numerous ovoid and round bodies some of the larger with modified centres of all shade of colour from clear to quite black. These bodies are not ova but we understand are of a calcium substance which forms gas on the addition of acid. They lie especially in and towards the invaginated head of the scolex. In other details the cysticerci resemble descriptions given in many textbooks. The cystic envelope or adventitious membrane is adherent to and formed from the surrounding brain tissue. As our microscopical findings do not conform to that which we understand is the more typical histological structure of this envelope we may report that sections of these complete cysts were made and each shows a very heavy cell infiltration around the connective tissue stroma and extending for a short distance into brain substance and when a free vessel is present a little beyond this perivascular infiltration is apparent. The majority of infiltration cells are plasma cells with fewer small round cells and a fair number of endothelial cells are also present while in one section two giant cells with massed nuclei are seen. The characteristic eosinophilia is present in one envelope only and red blood cells are extremely rare. In one section a small vessel on the external border of the envelope shows a moderate degree of endarteritis. In one envelope the sclerotic tissue is much developed and has a pronounced cell infiltration external to this. In this cyst only an occasional chalk body is seen in the cysticercus but a line of cuboid haematoxylin staining bodies are present.

(Our acknowledgements are due to Dr. C. Lovell and Mr. Crowe of Bethlem Royal Hospital Pathological Laboratory for their kind assistance in preparing the photomicrographs appearing as Fig. 2 and Fig. 3.)

COMMENTARY

Cysticercus cellulosae is excessively rare in this country. It occurs chiefly in eastern Europe, India, and South America. Its occurrence in man has apparently been known since 1558,¹ and there is scarcely an organ in which the parasite has not been observed. The brain is one of the situations most commonly affected. Thus in 155 cases of cysticercosis compiled by Stiles,² the brain was involved in 117, the muscles in 32, the heart in 9, the subcutaneous tissues in 5, and the liver in 2. In Diessel's series³ of 87 cases the brain was affected in 72 and the muscles in 13 while K. Müller, in 36 cases, found the parasite 21 times in the brain, 12 times in the muscles and three in the heart. In Vosgien's series⁴ the following was the incidence of the organs involved: eyes and adjoining structures 46 per cent, nervous system 40.9 per cent, skin and cellular tissues 6.32 per cent, muscles 3.7 per cent, and other organs 3.2 per cent. Titu Vasilu⁵ (1921), in an analysis of 330 cases of cysticercosis of the nervous system, described the brain and meninges as affected in 279, cerebral ventricles in 41, pons and medulla in 5, and the spinal cord in 5 cases.

In a prolonged experience of men disabled following temporary military service we have only once met with a case of cysticercosis, and in this case the cysts were in the subcutaneous tissues. Lieut. Colonel MacArthur, R.A.M.C., however, informs us that he has diagnosed clinically 5 cases of cysticercus infection with definite signs of central nervous system involvement amongst soldiers whose service in India and other places abroad has been more prolonged.

E. J. H. Roth⁷ records a remarkable case in a man, aged 44, who had suffered from epileptiform fits for ten years. The patient had served with the army in India from 1908 to 1911 and came under observation in 1926 on account of pain in the left knee-joint of about five years' duration, with a discharging sinus which had appeared two months previously. Cysticercus infection was diagnosed from the radiogram of the knee-joint, scattered throughout the muscles around the joint were numerous opaque and ovoid bodies which were undoubtedly of the nature of calcifications. Further radiograms showed a similar condition in nearly every part, but with the main grouping of the calcified nodules on the extremities as far down as the ankles and wrists. The diagnosis of cysticercosis was confirmed by excision and microscopical examination of one of the cysts from the right forearm.

C. J. Hill Aitken⁸ has recently recorded the case of a young man who had served in the army and complained of severe headache, diplopia, and "fits." Some small subcutaneous nodules were discovered, which on examination and pathological examination proved to be cysticerci.

Since von Graefe first demonstrated the presence of cysticercus in the vitreous of the eye, several similar cases have been recorded, and there can be no doubt that in the present case the enucleated eye showed the first symptoms of cysticercus infection.

When the brain is affected the symptoms are usually vague and general, and cases have been said to simulate hysteria, epilepsy, cerebral tumour, basal meningitis, and general paralysis. Transient tonic spasms and automatic movements have been described by Wollenberg. In Roth's case radiograms showed at least three calcified cysts lying in the pia mater, one was localized in the middle of the motor area on the left side. In the present case the main symptoms appear to have been those of focal epilepsy but with no constancy in the particular site affected.

Mental impairment is also a common symptom in cerebral cysticercosis, and usually consists of a simple weakness of intellect, conditions of excitement, confusion, and hallucination, however, have all been described. F. Hartmann⁹ has recorded severe disturbance of orientation, impairment of stereoscopic vision, and a form of mind blindness. Involvement of the fourth ventricle by cysticercus appears to be frequent, and in this situation may lead to sudden death. Cases have been recorded by Hammer, Meyer, Rothmann, and others, while Burns, Oppenheim, Gerhardt, and Henneberg¹⁰ have described combinations of symptoms arising from involvement of the cerebellum and medulla.

In the present case no involvement of the medulla was found. Extensive fibrous meningitis resembling gummatous basilar meningitis has also been described by Askunazy¹¹ Rosenblath,¹² Heuneberg,¹⁰ and others. As far as is known, the cysts are very little toxic, although it appears that pyrexia occurred at the onset of infection or early in the course of a case of disseminated cysticercosis described by Major R. Priest¹³ in 1926.

The case we record proved fatal after nearly six years of symptoms, but the parasites, especially when localized in the eye or brain, may live for long periods, very rare cases being noted up to twenty years (Kuchenmeister, Roth Ivanoff, Pfeifer, and others).

A CASE OF PNEUMOCONIOSIS RESULT OF THE INHALATION OF ASBESTOS DUST

BY

H. E. SEILER, M.B., Ch.B., D.P.H. Camb.,

ASSISTANT MEDICAL OFFICER, PUBLIC HEALTH DEPARTMENT GLASGOW

(With Special Plate)

THE asbestos industry has been in existence for over two thousand years, and it is remarkable that the possibility of damage to the lungs, arising from the inhalation of dust during its manufacturing process, has not been investigated until within comparatively recent years. Very few cases of pneumoconiosis due to asbestos dust have been recorded in medical literature, and for this reason the notes on the following case may be of some interest.

The first recorded case was that reported by the late Dr. Montague Murray of Charing Cross Hospital in 1900. No other case was reported, and the inference that asbestos dust might be the cause of an extensive pulmonary fibrosis was lost sight of for some time. In 1924¹ and 1927² Dr. W. E. Cooke published his exhaustive reports on another case, and described in detail the pathological changes and his "curious bodies," which are apparently a unique feature of the microscopical picture. This stimulated other investigations, and Simson³ has reported similar findings in workers employed in the crushing of asbestos rock, as apart from the manufacturing processes. In most of the cases hitherto reported the extensive fibrosis has been associated either with pulmonary tuberculosis or an unresolved pneumonia, and there has always been the slight doubt as to whether the inhalation of asbestos dust was the primary cause of the fibrosis.

The patient, a man aged 40 years, was sent for an opinion of his chest condition to the tuberculosis dispensary. The question of tuberculosis was raised as a consequence of his complaint of cough and breathlessness combined with loss of weight and lassitude extending over a period of several months.

Previous History.—There was no history of tuberculosis in the family. No history could be elicited of any illness in early life which might have led to a pulmonary fibrosis, and apart from the symptoms which he considered to be associated with his occupation as an asbestos worker he has had no other illnesses.

Occupation.—When a boy he had worked for a very short period in a glass works. Thereafter, for a period of twenty-two years he has been associated with the asbestos industry. During this period he has been employed in the various processes of

asbestos work. For four and a half years he worked at a carding machine, which is considered the dustiest part of the work for seven and a half years at the weaving of asbestos cloth, and for the remainder of the period at the manufacture of the millboard. The various processes differ considerably in their degree of dustiness, and therefore in the amount of asbestos dust inhaled by the various types of workers. As however a number of different processes, involving a varying amount of dust may be carried out in the same room, the dust produced at any one process may affect workers at another process. It will be noted that this man must have worked in the asbestos industry for a period during which less importance was paid to the prevention of dust than at the present time.

History of Present Illness.—The patient has had a cough from within a few months of starting work at asbestos, but he states that this was from the throat, and appeared to have been purely the result of dust irritation. Within recent years the cough has increased in severity, and there has been a little sputum first thing in the morning. The first symptom to cause anxiety was breathlessness, which developed five years ago and this has become accentuated since then. His general condition has remained satisfactory, and his particular symptoms were not sufficiently severe to interfere with his employment until a few months ago. At this time he complained of a steady loss of weight, frequent night sweats, and an occasional slight aching of the left shoulder. On no occasion has there been haemoptysis.

Notes on Examination.—He is a spare-built man, weight 7 st 11 lb, temperature pulse, and respirations within normal limits. No obvious dyspnoea noted on examination. Cyanosis of lips and cheeks, but not a marked feature. Well marked finger clubbing noticed by the patient for at least two years. Sputum scanty, and of a mucoid nature. Tubercle bacillus absent on frequent examination.

Examination of Chest.—Inspection showed expansion to be poor generally (one inch by measurement). There was hypertrophy of the extraordinary muscles of respiration, the supraclavicular fossae were markedly hollowed, the heart apex beat was in the fifth intercostal space within the nipple line. The percussion note was flattened throughout, there was relative dullness over the right upper lobe, both in front and behind. On auscultation the respiratory murmur was diminished generally, and of a harsh quality over the right upper lobe anteriorly and posteriorly. Expiration was prolonged all over the chest, rhonchi were general with fine pleural friction at both bases.

Other Systems.—Examination of other systems was negative.

X-ray Examination.—The radiogram of the chest shows a fine mottling of a silicotic type throughout both lungs, more marked on the right side and at both bases with indication of a definite fibrosis, especially on the right side. (See special plate.)

Progress.—The patient was admitted to hospital for observation, and has now been in-patient for six months. During this period his general condition has improved considerably, and he has gained over 1 st in weight. The cyanosis which had been noted on first examination has to a great extent disappeared, but there is still some evidence on the cheeks and lips. The cough which is now manifestly less troublesome, is still present, and there is a scanty mucoid sputum. Physical examination of the chest reveals no new feature apart from the absence of bronchitic sounds. The temperature and pulse remained within normal limits during the period of observation and treatment in hospital.

CONCLUSION

There seems little doubt that this is a definite case of pulmonary fibrosis, the result of the inhalation of asbestos dust. The recent development of symptoms of toxæmia, associated with long standing pulmonary symptoms, was at first suggestive of a chronic pulmonary tuberculosis with an acute exacerbation. However, the physical signs, the persistent absence of the tubercle bacillus in the sputum, and the maintenance of temperature and pulse within normal limits demanded further investigation. The typical radiographic features (signs more marked in the basal portions of the lungs) and his long period of employment with asbestos point definitely in the direction of a fibrosis of occupational origin, especially as there is neither a history of other illnesses in childhood or adolescence to support a more common cause of pulmonary fibrosis, nor does this correlation of history, symptoms, and physical signs occur in these latter cases. Toxæmic symptoms in the absence of a tuberculous affection are of special interest, whether they are the result of the absorption of some constituent of the asbestos rock or not is a point which requires further investigation.

AN ACHONDROPLASIC TWIN

BY

ALLAN WARNER, M.D., D.P.H.,

MEDICAL OFFICER TO THE LEICESTER MENTAL DEFICIENCY COMMITTEE,
AND SCHOOL MEDICAL OFFICER

IN an interesting communication on the etiology of Mongolism, which appeared in the *British Medical Journal* of June 30th, 1928 (p. 1106), Dr. Herbert Armstrong mentioned mentions that this form of mental deficiency is becoming increasingly common. After twenty-three years' experience of Leicester school children I had independently come to the same conclusion, so that any inquiry that would throw light on the cause and possibly lead to the prevention of this distressing condition would, I am sure, be very welcome.

In his article Dr. Armstrong records the case of a Mongol twin which he had recently seen, and, on reviewing the facts relating to it and similar cases, he comes to the conclusion that Mongolism is due to some maternal influence exercised upon the ovum during its maturation. In connexion with this case of Mongol twin it appeared to me that it might be useful to consider the causation of another form of imperfect growth—namely, achondroplasia—especially having regard to an achondroplasic twin that I saw at my clinic recently. The notes of this case are as follows:

Family History.—The father is healthy and his height is 66 inches. There is no history of dwarfism in his family. The mother is healthy and is 51 inches in height (her father was 74 inches in height). The great-aunt on the maternal side is said to have had a son who grew to adult life but always remained a dwarf and in many respects resembled the patient. The mother's first child, a girl, was born in 1903; she is healthy and is 65 inches in height. The second child, a boy, was stillborn in June 1916. The third and fourth children, two boys, were born in December 1917—the twins referred to above. The fifth child, a boy, was born in August 1919. He is healthy and is 52 inches in height, being about two inches above the average for his age. The sixth child was stillborn two years later.

Personal History.—Photograph No. 1 shows the twins aged 10½ years. The boy on the left was the first born and weighed 7½ lb. He is healthy and exceptionally tall for his age, being 60½ inches in height—that is nearly the height of an average boy of 14 years. Apart from his stature the only thing noticeable about him is that whilst his hair is a whole is brown he has a white patch about the size of a tennis ball and his father has the same defect. The boy on the right weighed 7½ lb at birth. He was very different from his brother in appearance with his peculiar head and flat nose. For the first three months he was less vigorous than his brother. He is quite intelligent and healthy apart from his achondroplasic condition. He is now 40½ inches in height. Photographs 2 and 3 show the head to be relatively large with well-developed frontal and parietal bones, the upturned nose, high arched palate (mouth breathing), the relatively long body, the short limbs with proximal segments shortened more than the distal, the short stumpy hands, the marked lumbar lordosis, the well-developed muscles and general thickness of the bones characteristic of achondroplasia.

It will be seen from the above notes that the first twin and the boy born at the subsequent pregnancy are exceptionally tall for their age, and it is probable that they will eventually be much taller than their parents. I have often noticed that a mother who is comparatively short, but who comes from a tall stock as in this case, transmits the character of tallness to her male offspring. This fact partly accounts for the stature of the first twin.

Although the twins are of the same sex, their physical characters are so remarkably different that they cannot be described as homologous or identical twins. Consequently it may be taken for granted that they were developed from

two distinct ova. In those circumstances the placenta may remain permanently distinct, but even in such cases fusion of the placental areas eventually takes place. It is generally accepted that the anastomosis of the placental vessels may be such as to result in marked differences in the general development and vigour of the two foetuses. This disparity is often explained by saying that the stronger foetus has made a special claim on the blood supply, which has enabled it to develop at the expense of the other. In the present case there was no great disparity in weight at birth, there was no general atrophy, but the smaller child had some special defect of the cartilages and bones. Even granting that this foetus had a smaller supply of blood than the other, it appears to me improbable that this could have had such a specific and selective effect.

Various theories have been suggested to account for achondroplasia. The resemblance of achondroplasia to rickets is so close that at one time they were thought to be the same morbid process, but Gilford¹ states that the points of difference are so great that most authorities now regard the two conditions as two distinct diseases. Mario² holds that the dystrophy of cartilage is an effect and not the cause, and that the disease is a general dystrophy comparable to myxoedema. On the other hand, Castin³ has pointed out that the disease starts *in utero* before glandular activity begins, and so cannot be due to any defective internal secretion. He believes that it is toxic in origin and is akin to rickets. Pelouquin⁴ and others believe it to be due to maternal infection. Neither of these views, however, appears to me to be in harmony with a case of twins where one child is normal and the other achondroplasic. The question of possible relationship between achondroplasia and gigantism has been raised by

Lannois, who reported an instance in which an achondroplasic had brothers who were giants. Since the interval between the births of the giants and the dwarf was very short, Lannois suspected the cause to be due to some discrasia on the part of the mother owing to frequent pregnancies. But this view does not seem tenable in the case of the achondroplasic twin, for the pregnancies were not very close together, and, further, the mother gave birth to an exceptionally healthy child at the same time as the achondroplasic one.

The question naturally arises whether achondroplasia is an inherited variation, to my mind this is probably the case, for there is no doubt that the condition is sometimes transmitted from parent to offspring. In 1913 I examined and photographed three dwarfs who were being exhibited at the Leicester Fair. The family consisted of father, mother, and daughter. The father was extremely small, though fairly well proportioned. The mother and daughter were typical achondroplasics.

Many similar cases have been recorded, but one published by Dr. Porter⁵ is extremely interesting.

In this instance an octogenarian and his two sons were affected, and the father and the brother of the former were also said to be achondroplasic.

In my experience achondroplasia is uncommon; its rarity is probably due to this useless variation being naturally eliminated in many cases by the death of the foetus owing to early ossification, or to the difficulties of parturition in the case of the pregnant achondroplasic woman.

THE TREATMENT OF RINGWORM OF THE SCALP
WITH THALLIUM ACETATE

BY

J. E. M. WIGLEY, M.B., M.R.C.P.

At the last meeting of this Section, held in Edinburgh in 1927, Dr G. B. Dowling read a very interesting and complete paper on the treatment of ringworm of the scalp by thallium depilation. Since that time many communications have been made from different sources, some being records of series of cases—for example, that by Dr Felden of New York in the *American Archives of Dermatology* of February of this year—others being notes of cases which have shown untoward or even alarming symptoms, such as that recorded by Dr Davies of Brighton in the *British Medical Journal* of July 9th, 1927. Dr MacLeod made a reference in a paper published in the *Journal* of April 21st, 1928 (p. 656), advising great caution in the use of thallium, and Dr McKenna, in the last edition of his textbook, is of the same opinion.

Now that a year has passed I think that the presentation to you of some of the opinions I have formed of the general utility or otherwise of this treatment will provoke useful discussion, and the conclusions arrived at should be of value in placing the treatment in its correct place in our therapeutical armamentarium. I do not propose to trouble you with lists of figures beyond saying that I have treated some 50 patients at two children's hospitals in London. Their ages have varied from 18 months to 9 years, and the sexes have been about equally divided. The dose of thallium acetate has been 8.5 mg. per kilo of body weight, given in an ounce of sweetened water. (The drug has been obtained from three different sources, but I have observed no material difference in the effects.) As all my patients have been attending hospital as outpatients the conditions may fairly be said to be exactly the same as those of the cases depilated by x rays in Dr MacLeod's clinic at Charing Cross Hospital, with which I compare them.

I have found that the average time for complete depilation with thallium is twenty-four to twenty-six days, and the depilation is entirely spontaneous in only about half the cases. In practically all the cases the infected stumps have been slower in falling than the healthy hair, whilst the recommencement of growth takes place very much sooner than with x rays. Here lies one of the chief reasons for which I regard the treatment as inferior to that of x rays.

Since Dr Roxburgh brought to notice (in March, 1927) the method of detection of hair infected with ringworm by its fluorescence when illuminated by ultra-violet light passing through Wood's glass, I have been in the habit of checking all my "cures" by this method, and frequently with a very salutary effect. The routine use of this method has brought to light two facts which I have never seen reported and which are of some considerable importance. The first of these facts is that one frequently finds full-length, apparently healthy hairs fluorescent for the whole of their length. Examination of these hairs with a hand lens reveals no abnormality, nor do they appear to break more easily or to be more difficult to remove with forceps than normal hairs. Microscopical examination of these fluorescent hairs invariably showed the presence of ringworm fungus, and culture on several occasions further confirmed this. The importance of this observation will be referred to later.

The second fact I have observed is that hairs fully infected with endothrix ringworm completely failed to fluoresce. In these hairs the cuticle of the hair was seen under the microscope to be quite intact, which fact, I take it, explains the absence of fluorescence.

The point of this apparent digression becomes evident when the rapidity of regrowth after thallium depilation is considered, together with the difficulty of removing every single stump, some of which may not have been loosened by the drug. I have more than once failed to find evidence of infection by means of the microscope in a scalp

apparently satisfactorily depilated by thallium, and yet by means of Wood's glass have seen the full-length fluorescent hairs just described. This difficulty I have not encountered in the cases treated by x rays. Here I would like to say that the point I am making is not that x-ray treatment is infallible (it is too well known that it is far from that), but that its failures are not deceptive. I have never had any difficulty in immediately seeing the unfallen stumps in an under-exposed scalp, whereas I have just been at some pains to show that the failure of thallium depilation may camouflage itself very effectively.

Great stress was laid by Dr Dowling and by several other writers on the importance of vigorous local treatment during the period of falling and recommencement of growth of the hair, and of this I am fully aware. But nearly all cases of ringworm are treated as outpatients, and as a rule are not seen more than once a week. Consequently most of the local treatment must, of necessity, be left to the mother, who, largely through force of circumstances, can seldom carry out the treatment satisfactorily. I have had the scalp painted with strong tincture of iodine, have used adhesive plaster, have ordered 12 per cent sulphur and salicylic acid ointment, Whitfield's ointment, the iodide of sulphur ointment to be rubbed in, but have not been impressed with their power to combat the uncertainty of the depilation produced by the drug.

With regard to toxic symptoms, I have been struck with the fact that the older the child the more certainty is there of toxic symptoms supervening. Pain in the legs, usually coming on about the twelfth day and lasting about a week, is the most common symptom. It quickly responds to rest in bed, and seems to be of negligible importance. Drowsiness I have noticed in several cases, and have observed that such children were always of the pale, flabby type, though nothing abnormal was discovered on clinical examination. One case is worth reporting more fully.

The patient was a boy aged 9 who was in hospital suffering from a generalized dermatitis associated with seborrhoeic dermatitis of the scalp. He was given a dose of thallium acetate with the object of attempting to clear his scalp. About twelve days afterwards he exhibited an acute erythematous eruption on his forearms, the backs of the hands, and the shins. His temperature rose to 101° F and he was definitely ill. His hair all fell towards the end of the third week, his temperature subsided and the rash disappeared. Unfortunately the condition of his skin was unchanged. The sequence of events seems to me to point to some auto-intoxication the action of the thallium being to lower his resistance at the time.

A case reported by Drs J. H. T. Davies and M. C. Andrews in the *British Medical Journal* of December 17th, 1927 (p. 1139), presented somewhat similar though much more alarming symptoms. This patient, a girl of 11 years, showed swelling, redness, and tenderness of the legs with effusion into both knee-joints. On the eighteenth day the child had an epileptiform fit and was found to be febrile, to have some ascites and evidence of acidosis, as shown by acetone bodies being present in the urine. A much older patient of Dr Davies suffered from loss of sensation in the legs and feet, associated with inability to walk, so that a diagnosis of peripheral neuritis was actually made.

It seems to be established that thallium acts through the sympathetic nervous system, and these cases show how seriously that may be affected. Whether such affection is purely temporary or not time alone will show, but until it is proven I think we should be very chary of risking the development of children in order to cure (by no means with "certainty") a purely local infection.

In conclusion, I think that thallium acetate is distinctly inferior to x rays (in the hands of a skilled operator), for the following reasons:

- 1 The relative uncertainty with which it produces the desired effect—that is, depilation.
- 2 The slower fall of the infected hairs and the short time elapsing before recommencement of growth.
- 3 The necessity for more skilled and vigorous local treatment during this time.
- 4 The greater risk of reinfection of the growing hair owing to the short time of baldness.
- 5 The toxic effects produced by the drug.
- 6 The possibility of permanent serious damage to the growing organism.

Memoranda : MEDICAL, SURGICAL, OBSTETRICAL.

A CASE OF DIAPHRAGMATIC HERNIA (EVISCERATION) (With Special Plate)

THE following details of a case of diaphragmatic hernia caused by trauma seem worthy of record, the nature of the injury is clearly indicated in the illustration

A man aged 64 was sent to one of the tuberculosis visiting stations as a case of spontaneous pneumothorax after an x-ray examination had been made at a local hospital. The clinical history and physical signs did not altogether fit in with this diagnosis, and the patient was sent to the hospital at Cefn Mably where he was screened and given a barium meal by Dr W. Davies the medical superintendent. The true nature of the case was then made plain.

There was a history of a severe crushing of the abdomen and chest by an accident in a colliery forty years previously. For more than three months the patient's life was said to have been in jeopardy but he eventually recovered sufficiently well to resume his occupation of a coal miner. Throughout the subsequent years he enjoyed good health with the exception of occasional attacks of vomiting and of dyspnoea on extreme exertion.

During the winter of 1926 an attack of influenza compelled him to visit his medical attendant who discovered the unusual condition of his chest and came to the conclusion that the case was one of spontaneous pneumothorax.

The physical signs were certainly very suggestive of this condition, but they varied in character and extent when the patient was in the recumbent position. 'Gurgling' could also be heard when he was lying down. The cardiac impulse was well over to the right side of the sternum and its position did not vary. No evidence of pulmonary tuberculosis was forthcoming.

That such an abnormal condition should have caused so little inconvenience during so many years is of very great interest.

Newport Mon

J. L. THOMAS, M.D.

THE TEAR-REFLEX TEST FOR ASTHMA OF NASAL ORIGIN

I DESIRE to submit to the medical profession a test for asthma of nasal origin to which I attach considerable importance. It is, in my opinion, a ready and reliable way of differentiating between nasal and other forms of asthma. I have used it successfully for six years.

Definition

The Tear-reflex Test—In a normal nose, if the anterior mucous surface of the nasal septum or inferior turbinate bone be gently stroked with a smooth silver probe no reflex is produced, but if the same thing be done in a patient suffering from asthma and produces lachrymation in the eye on the same side as the nasal fossa so tested, but not in the other, then the asthma is of nasal origin, and is usually curable. (This test should be applied by exposing and illuminating the nasal fossae for examination in the orthodox manner.)

Anatomy and Physiology

This reflex has no emotional significance, but appears to be confined to the first or ophthalmic division of the fifth nerve. It starts in the medial or lateral nasal nerves which supply the anterior parts of the septal and lateral nasal mucous membranes respectively, and passes to the lacrimal gland by way of the lacrimal nerve. It is possible that a few impulses from the inferior turbinate bone pass through Meckel's ganglion. Its homolateral significance will no doubt be appreciated.

This test is one for a hypersensitive condition of the nasal mucous membrane, to which I believe the "nasal reflex" type of asthma is due. Where it is positive a cure may confidently be expected by using the orthodox methods of nasal desensitization and surgery. Where it is negative the outlook is less hopeful, even though the nose may stand in urgent need of treatment, because the nasal condition may be so bad that superficial sensation is lost. On the other hand, where it is negative and the nose is approximately normal, the cause may be looked for elsewhere.

H. MORTIMER WILKINSON, F.R.C.S.

AN ATAVISTIC ANOMALY SWALLOW WINKING
Cases of "jaw winking" and its allies are sufficiently rare to warrant the reporting of the following case.

A Jewish boy aged 2 was admitted to Booth Hall Infirmary for Children as a case of pertussis. The nursing staff reported that he had exophthalmos of the right eye when he coughed or swallowed. Examination showed no obvious abnormality of the eyes or the palpebral fissures. The movements of the eyelids and of the eyes were normal. Chewing made no difference but as soon as the child swallowed the right palpebral fissure was distinctly enlarged by the retraction of the upper eyelid. In other words the child winked but the wink was upwards giving rise to a very curious appearance.

Cases of associated movements have been reported for a very long time. Dr. Rutherford of Manchester has kindly given me the following references: (1) It may be that Galen, *De Medicina* vi, 6, 36, refers to this, but the condition he mentions may quite possibly be nystagmus. (2) Martin Martin, in his *Description of the Western Isles of Scotland*, the second edition of which was published in 1716, on page 191 writes that "a weaver in Portree has the faculty of erecting and letting fall his ears at pleasure, and opens and shuts his mouth on such occasions."

Mr. Bishop Hurman, who investigated this phenomenon in 1903, has kindly referred me to his explanation in the *Transactions of the Ophthalmological Society* for October, 1905, assigning it to the origin of the nerve supply of the associated muscles to the seventh nerve.

The first case recorded, by Gunn, was one in which the upper eyelid nearly went out of sight when the child sucked, but this case of similar palpebral action only on swallowing appears to be an additional variety.

JOHN D'EWART, M.B. LOND.
Medical Superintendent, Booth Hall Infirmary
for Children, Manchester.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

OXFORD DIVISION

The Clinical Signs of Mammary Disorders

THE fifth meeting of the year of the Oxford Division was held at the Radcliffe Infirmary on October 24th. In the absence of Dr. G. N. Montgomery the chair was taken by Mr. F. C. BEYERS, and Sir G. LENTHAL CHEATLE read a paper on the clinical signs of important changes in the breast.

Sir Lenthal Cheatele pointed out that some pathological changes in the breast bore a definite relation to simultaneous physiological occurrences. The normal structure of the breast included (1) the pericanalicular and periacinous connective tissues round all ducts and acini, (2) the elastica which surrounded all ducts, occasionally some acini, and less frequently the lobule, being continuous with the elastica of the skin, (3) inside the elastica was the intra-elastica connective tissue continuous around all ducts and acini, and (4) superficial to this last, and lining all ducts and acini, was the epithelial layer resting on a single layer of unstriated muscle fibres. These structures formed the true breast tissue and were the sites of true pathological changes in the breast. They were embedded in the dense supporting connective tissue of the breast, which had little or no relation to any pathological changes, although it might be subjected to the same pathological changes which occurred in supporting connective tissue elsewhere in the body. At birth, puberty, and lactation, the pericanalicular and periacinous tissue underwent varying degrees of hyperplasia in which lymphocytes could be observed. New normal ducts and acini also formed at these times. At puberty fibro-adenomatous developed, and were composed of an excessive hyperplasia of those tissues which were undergoing normal hyperplasia in the breast. In them there was a very marked growth of pericanalicular and periacinous tissue among which new ducts and acini could often be seen, these were lined by the normal epithelium, which in some instances was undergoing a desquamative epithelial hyperplasia. These tumours were

lobulated because fresh areas of the breast in juxtaposition to, or a little distance away from, the original tumour became affected in the same way, so that lobulation was not due to an outgrowth of tumour formation from the periphery of the original tumour. The comparison between these tumours and the physiological changes occurring in the breast elsewhere was complete, and an etiological connexion was too true to be neglected. Breasts at birth had not completed their development. The solid columns of epithelium which dipped down into the gland and formed the secreting parts of the gland sometimes appeared morphologically as malignant because they were not confined within the barriers of normal tissue. More often in the breasts of married women who had borne children than in single women there appeared, between the ages of 35 and 45, a state that was generally described as "chronic mastitis." The condition was not inflammatory, and to distinguish it Sir Lenthal Cheate stated that at the suggestion of Sir Humphry Rolleston he had termed the state "mazoplasia." The microscopic appearances of mazoplasia were distributed over the whole gland, in some parts they might be more marked than in others. They consisted of a hyperplasia of the poracanalicular and periacinous tissue among which lymphocytes were seen. New acini might be formed, and in the ducts and acini a marked desquamative epithelial hyperplasia might develop, giving rise to distension of these structures and causing pain. The desquamative epithelium consisted of small, irregular, badly staining epithelial cells. These changes were precisely similar to those at puberty and lactation and in some respects also at birth. They were pathological only in respect of their irregularity and their appearance at a time when the breast should be at rest. Moreover, the breasts in mazoplasia resembled the changes at puberty in developing fibroadenomata, which consisted of the same tissues as the fibroadenomata of puberty. The multi-nodularity of these breasts was not due to changes in the gland itself, but to their becoming more pendulous, especially after lactation, the ligamenta suspensoria became thicker, and as their branches reached the true skin they isolated the fat between them into lobules. Recognition of the precise cause of all multi-nodularity therefore required discrimination. As a general rule it was not an important sign, but it might be due to a rare state of diffuse mammary carcinoma and multi-cystic formation of the breast. Mr. Cutler of New York had introduced transillumination as a valuable means of diagnosis in breast diseases. In mazoplasia and multi-cystic disease the breast was completely translucent, in carcinoma whether localized or diffuse, there was a distinct shadow. In multi-cystic disease the swellings varied in size and the largest ones gave a distinct sensation of fluctuation. Cystic formation in breasts and mazoplasia were quite distinct and separate conditions. The epithelial changes in the two conditions were morphologically different, and very frequently the desquamative epithelial hyperplasia which was so remarkable in the formation of cysts could be seen passing into that much more important form of hyperplasia which was not desquamative, and which Sir Lenthal Cheate had named "dysgenetic." Such dysgenetic epithelial hyperplasia occurred in three different states: (1) the formation of papilloma, (2) the formation of epithelial growth in terminal ducts and acini, confined within normal boundaries and (3) in the state of carcinoma where some cells had invaded structures outside normal boundaries. Therefore the formation of cysts was not only a different process to mazoplasia, it was also a more dangerous condition. In thin breasts multi-nodularity was also caused by ducts which had become convoluted after lactation and diffuse hyperplasia of the elastic element in their walls. Multi-nodularity was therefore not a very important sign. Where localized nodularity or a lump in the breast was discovered its nature should be established at once by an exploratory operation, undertaken with very great care in order to prevent transplantation of epithelial cells should the condition be malignant. A retracting nipple never occurred in mazoplasia, it might be due to a carcinoma immediately under the nipple or on advanced carcinoma some way from

it, and it might also be caused by an inflamed cyst or tuberculosis. The diagnosis between these states in the case of a cyst was settled by transillumination, which in carcinoma and in tuberculosis would show a shadow. The diagnosis of tuberculosis of a breast was not always easy, before it reached the skin this might be puckered. The nature of the disease was made clear when it reached the skin and appeared as a soft, blue prominence. Moreover, lymphatic glands secondarily affected by tuberculosis differed from the glands secondarily affected in malignant disease by immediately becoming confluent in tuberculosis and remaining for a long time as hard, discrete lumps in malignant disease. Puckering of skin by an underlying swelling was also a symptom of fat necrosis, and it was difficult to distinguish clinically between it and early carcinoma. Puckering of the skin over a swelling was so serious a sign that it indicated an exploratory operation. The lecturer drew attention to the importance of an intermittent, spontaneous discharge of blood or serum from the nipple, both of which, in the absence of any traumatic cause, were indications for removal of the breast. Another important sign was localized pain, especially of a stabbing nature.

Clinical Cases

Mr. W. W. WAGSTAFFE showed a boy, aged 10, who had had a tumour removed from the dorsum of the tongue four years previously. During the last year a swelling had been noticed on the dorsum of the tongue on the site of the old incision, and in the course of the last few months it had been growing very rapidly. He had no pain, but the size of the swelling caused some discomfort. On examination a swelling was found on the posterior aspect of the dorsum of the tongue, extending about two inches forward from the foramen caecum, and with a breadth of about one and a quarter inches. It stood out from the surface of the tongue about three-quarters of an inch at the greatest part, but at the posterior end the swelling projected considerably backwards. There was no interference with the mobility of the tongue, and no enlarged glands could be felt. In the absence of the original section it was impossible to say what was the nature of this growth. It felt firm and rather fibromatous, and the epithelium was somewhat thickened over it, but it had no papillomatous appearance. It did not appear to show an excess of blood vessels. A provisional diagnosis of either a fibroma or an endothelioma was made. As regarded treatment, excision once had been unsuccessful, and would be extremely difficult now. It was suggested that the growth should be destroyed by means of diathermy.

Dr. SHIELA HUNTER showed a female patient, aged 43, who had developed pulmonary tuberculosis subsequent to old rheumatic valvular disease of the heart ("mitral stenosis"). She also read notes about a man, aged 32, who had been treated in the Osler Pavilion during the past year. This patient was refused for army service in the war because of his heart, but it was only comparatively recently that signs of pulmonary tuberculosis had developed. In both cases there was gross valvular disease of the heart and tubercle bacilli were found in the sputum.

Dr. W. STOBIE read notes about a girl, aged 12, who had suffered from pneumonia and empyema at the age of 4. There were signs of interstitial fibrosis and probable excavation at the base of the left lung, but owing to the density caused by the heart shadow an ordinary x-ray film revealed nothing definite. A film taken after the use of lipiodol, however, showed two definite dilated sacs behind the cardiac shadow.

Mr. E. C. BEVERS showed a man, aged 56, suffering from an abdominal tumour. For three months he had noticed a swelling in his right iliac fossa, there being no pain and no bowel symptoms of any kind. On examination a hard, fixed swelling was found in the right iliac fossa, extending upwards in the line of the ascending colon and downwards to within one inch of the middle line. The swelling was very hard, and in one place appeared to be invading the abdominal wall. Both the barium meal and barium enema showed a filling defect in the region of the caecum and ascending colon. The diagnosis rested between a retroperitoneal sarcoma and a malignant growth of the caecum which had invaded the abdominal wall.

Dr A. G. GINSON showed a farm laborer, aged 20, suffering from a sudden pain in his left hip, which prevented him working five days after the onset. He had a sudden swelling in the tongue. Dr Bostock of Buckingham found an enormous swelling and haemorrhagic condition of the jaw and tongue on the right side, causing difficulty in mastication. There was also haemorrhage in the region of the left ilium, where there was a swelling above Poupert's ligament in the hollow of that bone. There were numerous petechial haemorrhages elsewhere. The patient was very ill, with a high temperature and an overaction of the heart that suggested a cardiac lesion. Within a few days he rapidly improved, the temperature subsided, and all traces of haemorrhages disappeared from the skin and mucous membranes. The blood culture was negative. There was no trace of haemophilus in the previous or family history, and no evidence of scurvy, leukaemia, thrombocytopenic purpura, or cardiac disease. An x-ray investigation of the swelling of the ilium showed no bony change, but there was an old slipped epiphysis of the head of the left femur.

Reports of Societies.

JUVENILE DELINQUENCY.

At a meeting of the Medical-Legal Society on November 22nd, with Sir WILLIAM WILCOX in the chair, Dr LOVELL A. WEATHERLY of Bournemouth opened a discussion on juvenile delinquency.

Dr Weatherly confined his argument to those juvenile delinquents who, by reason of some anti-social act, had been brought to police courts or the juvenile courts, saying that in trying to enquire the mental growth of the average child and must be sought from physiology, the science of the function of the organism, pathology, the science of disease, sociology, the science of human society, and psychology, the science of mental phenomena. A multiplicity of contributing factors would generally be found in any instance of juvenile delinquency, but in each case a major cause presented itself. As to physiology, any physical ill development, causing, for example, an infirmity of sight or hearing, or some deformity, led to the sufferer being dominated by his physical handicap, and unless compensated by training or education, or comforted by sympathetic treatment, he might drift into crime. The late Mr Thomas Holmes, the well-known police court missionary, declared that in his long experience the most serious cases of crime were far more physiological than psychological in their basis. Again, to take pathology, dementia praecox made its victim subject to sudden inexplicable impulse, as a rule of an aggressive and destructive kind. Many children who suffered from epilepsy showed no anti-social or immoral activities, but this disease often did lead in the young to (generally motiveless) crime. Encephalitis lethargica, again, completely altered the character of the young people it attacked, and was now considered a certifiable disease under the Mental Deficiency Act. A peculiar morbid condition sometimes occurred in the young after injuries to the viscera of the abdominal cavity, or after an abdominal operation sometimes sexual perversion developed. Under the present beneficent system of probation and with the establishment of observation centres, the early mental condition in these pathological cases should be revealed, and proper care, training and treatment carried out. The cases of delinquency which might be grouped under the heading of sociological causes included those due to defective discipline, family history of vice, incapable parents, bad companions, too much amusement or lack of it, or defective family relationships, such as bad step-parents. There remained the psychological class, in which the speaker grouped the subnormals or moral imbeciles, many of whom were not deficient enough for certification under the Mental Deficiency Act. Most of these subnormals required some method between Home Office schools and Borstal institutions on the one hand, and simple supervision under the probation officer on the other. For some years he had advocated for these cases farm colonies, where other trades

might be taught, these should be established by a combination of philanthropy, State aid, rate aid, and self-help. Occupation therapy would be the keynote of the treatment. Dr Weatherly then sketched the immense change which had come over public opinion in relation to juvenile delinquency of recent years, seen particularly in the introduction of juvenile courts, Home Office schools, and probation officers. Recently, at a meeting of the Magistrates' Association, Sir Robert Wallace stated that 85 per cent of the boys and girls put on probation did not again relapse into crime. Probation, Dr Weatherly considered, was the greatest advance ever made in penal reform, but probation should always be conditional. The great handicap to probation was the absence of a home or institution for cases which could not possibly be supervised in their own homes. The difficulty that beset the Home Office was that while Acts might be passed, and suggestions and proposals made, there were no means of enforcement. The want of uniformity and the disposition not to act upon many of the Home Office's excellent proposals might be attributed to financial causes, to bias on the part of the magistrate or perhaps his clerk, and to the inherent dislike of interference with local authority. The suggestions of the Home Office should be made in some way imperative. Dr Weatherly, after a tribute to the Salvation Army, the St Giles's Mission, and other voluntary organizations, concluded with the remark that the objective was to get hold of "difficult" children when young and take them out of the danger zone in which anti-social acts were conceived, to recognize the inutility of sending young offenders to prison, where they were contaminated by adult offenders, and to insist upon kindly and careful supervision whereby they might have a proper start in life.

Lord RUSSELL said that he was sure many cases of delinquency could be explained not as conscious and intentional or criminal tendencies but as the result of some psychological or physiological, or it might be sociological, defect in the upbringing. The one thing that should not be done was to send these offenders to prison. He believed the Home Office circulars and admonitions were now having effect among the country magistracy. Dr T. B. HYSLOP raised the question whether it was a greater handicap to be sent to a prison or to be sent to an asylum. The prison might represent the frying-pan, and the asylum the fire. An asylum history extended its taint—for which, of course, there was no scientific basis—even to the third and fourth generation. He was glad to see rather more enlightenment in the courts, which had previously been difficult to persuade that some crimes might be committed in the subconscious state. Lieut.-Colonel C. T. SAMPSON thought that some juries were very much too lenient towards young offenders. Previous to committing his offence a boy knew perfectly well that if he could tell his counsel that he had never before been convicted he would probably only be bound over.

Dr W. A. POTTS (Birmingham) said that many cases of juvenile theft were simply the result of an imperfect and misleading education. A child brought up in an extremely poor home, where everything was possessed in common, was likely to have little understanding of individual possession when he went to school. Sometimes the fault was over-emphasis of one particular warning to the disregard of other phases of conduct. A boy at a preparatory school had been discovered in apparently motiveless stealing. In conversation with the lad's father the speaker asked him if he emphasized any particular principle of ethics in dealing with his son, and the father on reflection said that he had instilled into him continually the necessity of having nothing to do with the hire-purchase system! Encephalitis lethargica was a very important cause of many cases of delinquency. The initial attack was sometimes so slight that a doctor was not called, or, if he was called, did not realize what the nature of the illness was. Juvenile courts were valuable, but sometimes there was a danger that the mere establishment of such a court would be taken to have settled the problem. The mind of the child could not be reached in the public court with various officials about. Probation was also an important reform, but it should be continued until the offender was found satisfactory. It was ridiculous to think that six months' probation would

be sufficient. Mr W. A. CHADWICK pointed out the importance of checking early delinquency in the home among very young children. The important thing was to instruct parents in dealing with difficult psychological cases.

Dr R. G. GORDON (Bath) said that very often in the home the young thief of 6 or 7 was regarded either as having performed an amusing trick or as having done something too shocking to talk about. Such abnormal conduct required advice, not putting under a blanket. There was need for advisory clinics to which children with social tendencies could be brought. The difficulty in almost all cases was failure of adjustment between the child and society. Some institution was wanted in which there was a system similar to that of the industrial school, but to which children might be sent, not only from the police court, but through any responsible body interested in this work. There was a tendency to regard subnormality—a certain degree of feeble-mindedness—as the chief cause of delinquency. It was an important contributory cause, but not by any means the only cause. The real factor seemed to be a lack in the normal development of the personality of the child.

Dr F. C. SHRUBSALL said that the British juvenile population was probably the most law-abiding in the world, but there was more delinquency now in this country than formerly, when the personal influence of the schoolmaster counted for more. Classes were now so huge that this personal influence was no longer possible, clinics offered a substitute. Once a child got even into a juvenile court it was too late to handle the problem as it should be handled. Dr L. FAIRFIELD, speaking with regard to industrial colonies for these children, said she hoped no one would suggest they were going to pay for themselves. They were as expensive relatively as the Ritz Hotel. They were only worth having if they were well run, the children well fed, and the supervision of the highest quality, and under the British system this could not be done cheaply. She described clinics on the American model, with careful investigation of the child as their aim, one or two of which already existed in London, while a very well equipped one was to be started in London next year under the Child Guidance Council. Lord RIDDELL thought that many of the "subnormals" might be improved if they received intelligent modern medical treatment. It was most important that the medical profession—the general practitioners in particular—should be trained in these matters, so that an abnormal child might be treated without having to be sent to a clinic. Dr ELIZABETH SLOAN CHESLER spoke of her visits to prisons in various parts of the world, she praised the Japanese system, where 80 per cent of the first offenders were so treated as not to relapse. She emphasized also two things which had not been so much as mentioned in the discussion: (1) the education of mothers, (2) decent housing.

ANTE-NATAL METHODS AND DISPROPORTION

A MEETING of the Maternity and Child Welfare Group of the Society of Medical Officers of Health was held at the Royal Free Hospital on November 23rd, with Professor A. LOUISE McILROY in the chair, to discuss ante-natal methods, with special regard to disproportion.

Mr B. LINDLEY HOLLAND commented generally on the value of ante-natal clinics, and remarked that far more women lost their lives or suffered injury in consequence of lack of care during labour than for the want of ante-natal care. There was need for the institution of more large maternity hospitals, such as Queen Charlotte's or the Rotunda, Dublin. As regards the difficulty due to disproportion he suggested that external measurements ought to be taken, if only because they gave an early idea of the kind of labour a patient was likely to have, he also believed in fairly early vaginal examination. It was stated in textbooks that in the primigravida during the last months of pregnancy the head was, or in all normal cases should be, engaged in the pelvis. The fact was that in about 20 per cent of primigravidae in the thirty-sixth to the thirty-seventh week of pregnancy the head was still unengaged, and it should not be assumed that there was dis-

proportion merely because, at any time during the last four weeks of pregnancy, the head was floating. In deciding what was the right proportion the reserve capacity of the pelvis was important. A woman with a normal pelvis could give birth to an infant up to the weight of 10 or 11 lb, the normal being 7½ lb, it would be a difficult labour, particularly if the first, but there should be no great obstacle. The pelvis accomplished the task by calling up its reserve capacity. It followed that if a normal pelvis would allow the passage of a 10½ lb baby a slightly or moderately contracted pelvis would allow the passage of a 7½ lb baby. There were two methods of treating the slighter cases of disproportion: induction of premature labour, or allowing the patient to go to spontaneous labour at term, how was known as a "test labour," and adopting Caesarean section early in labour if delivery by the natural passages was considered unlikely. The former was the time-honoured method in this country, but for some time he had been rather doubtful whether it was the best. He believed that in 80 per cent of the cases induction of premature labour was performed unnecessarily, and at the London Hospital he began to try the other method mentioned, with improved results. To induce premature labour was to play for safety. The only known factor was the disproportion, yet there were a large number of unknown factors which, if favourable, might lead to spontaneous delivery. His method in moderate or slight cases of genuine disproportion, where the pelvis was shown by measurements to be contracted—he excluded all cases of merely floating head without disproportion—was at the thirty-sixth week to attempt to decide, often with the help of an anaesthetic, whether the patient should have Caesarean section at term or whether there was a reasonable chance of spontaneous or forceps delivery. The object of the test labour was to decide, very early in labour, whether the head would come through the pelvis or not. He mentioned various conditions which pointed to the need for Caesarean section, and said that, in 1927, out of 16 test labours at the London Hospital, spontaneous delivery occurred in 11, easy forceps delivery in 3, and Caesarean section was performed early in labour in 2. All the infants, except one, were born alive, and there was no maternal mortality.

Dr ANNIE McCALL spoke of the importance of dieting the mother so as to prevent the osseous development of the child's head beyond a certain point. The mother was kept off protein diet during the last month or two months of pregnancy, not was she given milk, which tended to produce fat infants. Her digestive troubles were minimized by the sipping of hot water, and she was allowed to eat fruit to any extent she liked. Exercise was also important during the last two months, and every day the woman ought to walk not less than three or four miles, preferably uphill. Dr McCall endorsed entirely the observations of Dr Kathleen Vaughan in the letter published in the *British Medical Journal* of November 17th (p. 812). Hot baths—no hot as could be endured—should be taken every day during the last month and every other day during the preceding month. She liked to give chloral hydrate every night or every other night during the ten days before labour. This made the first stage of labour a good deal easier, and so the mother was able to reserve her strength for the second stage, in which she was assisted by the softness of the pelvic floor induced by the hot baths. By hot baths, also, the danger of eclampsia had been wiped out. The speaker recited some lines which were used in the Clapham Ante-natal Service to impress these measures upon the women:

In later months of pregnancy dispense with eggs and meat,
Then drink hot water freely, take fruit—all you can eat.
Hot baths are very useful, their value is untold,
These rules with daily exercise, are worth their weight in gold.

Professor F. J. BROWNE agreed with Mr Holland that in a large number of primigravidae the head might be floating above the pelvic brim and still no pelvic contraction be present, he thought it might be specified that in these cases the condition was not always normal. In his own experience it was in a very small proportion of cases—certainly far less than 20 per cent—that the head failed to engage without any ascertainable cause. He was satisfied that induction of labour was the method of treating

these cases. "Trial labour" was not used at University College Hospital. Mr Holland had criticized induction of labour as "playing for safety", but what else should one play for in labour? The trial labour was impossible in private practice, how was a busy general practitioner to watch such a case, listening to the foetal heart every hour? Induction of labour also caused far less anxiety, it was safe to induce labour at a date after thirty-six weeks, when the head, in the average case, was so hard that there was a fair chance of its passing without injury through the maternal passages. If there was found on examination definite overlapping of the foetal head over the pelvic brim induction of labour was contraindicated, it was his practice to allow the case to go to term and then perform Caesarean section.

Mr ALEX BOURNE remarked that disproportion could only be absolutely defined after birth. The infant with the over-moulded head was nearly always found in one type of pelvis. It was not the size of the pelvis which was so important as the shape, and it was because pelvic measurements rendered the shape ascertainable that he disagreed with those who said that they were useless. If the head overlapped just the thickness of the symphysis that head would almost certainly come through, but if it actually overhung the symphysis it would mean so much moulding that the child's life would probably be lost. As regards treatment he was a strong supporter of induction, in private practice trial labour was almost impossible. Its undertaking meant telling the patient and her relatives that at a critical time in labour it might be necessary to rush her off to hospital—a terrifying thing to her and to them. The importance of the error of inducing labour unnecessarily early—though never before thirty-six weeks—was less in his eyes than the error of letting the woman go to term too late, with difficult delivery or an unnecessary Caesarean section. Of the three errors he would prefer the first.

Mr CEDRIC LANE-ROBERTS supported Dr McCall's contention that the protein diet should be cut down during the last weeks of pregnancy. On the question of trial labour *versus* induction, if midwives co-operated with doctors in taking their patients to the ante-natal clinics the floating head would be likely to be discovered by the doctor at the clinic, and the case would be met by induction rather than a trial labour, which involved much anxiety.

In further discussion Dr MAX KIDD spoke of the need for a reliable drug to induce labour, quinine not being reliable, to which Mr ALEX BOURNE replied that experiments on now preparations were proceeding but he had examined the action of quinine on the contracting uterus by the introduction of a hydrostatic bag and found its effect no more than to make the contractions irregular, he thought quinine quite useless for the induction of labour. Dr LEWIS NASH, speaking as an administrator, protested strongly against any idea that midwives should have anything to do with inducing labour. Dr CHODIE GRECONY, referring to Dr McCall's diet for the pregnant woman, which was practically carbohydrate, asked how the child obtained the necessary iron. Dr ITHY CASKIE (Birmingham) thought that disproportion cases must be relatively few, and that it should be possible to make institutional provision for them all. Professor McILROY said that at the Royal Free Hospital induction was performed very rarely before the thirty-eighth or thirty-ninth week, the majority being at term. It was not forgotten in teaching students there that the greater number of them would be concerned with domestic, not hospital midwives. The funnel shaped pelvis seemed more common in London than in Glasgow. She described some tests on the reserve force of the pelvis which were being made at the Royal Free Hospital.

Mr CARDLEY HOLLAND, in reply, agreed that trial labours were not suitable for general practice, but only in institutions. The method was in vogue chiefly in countries such as Switzerland, most of Germany, Scandinavia, and large parts of America, where most of the midwifery was conducted in institutions, and few women were confined in their own homes. He had not the least doubt that that would eventually come to pass in this country.

Rebucius.

THE EVOLUTION OF MAN'S BRAIN

STUDENTS of man's evolution have been looking forward to the appearance of Professor TILNEY's book entitled *The Brain from Ape to Man*.¹ Rather more than a year ago Dr H. LAMBERT OSBORN, who contributes a preface to it, took them by surprise by declaring that man's relationship to anthropoid apes was of the most distant kind: man and ape, he informed them, had parted company at that remote geological period which saw the first appearance of primate animals. Dr Osborn accounted for the many and close structural resemblances between man and anthropoids not by descent from an immediate common ancestry, but by evolution working in both the anthropoid and human lines of descent in a parallel direction. An opposite view was taken by Dr W. K. GREGORY, who is Dr Osborn's chief lieutenant, and has devoted thirty years to a study of all known fossil remains of primates and of man. His studies have convinced him that the palaeontological and anatomical evidence can be explained in only one way—by accepting the Darwinian hypothesis that man and anthropoid have been evolved from the same stock in a recent geological epoch. In this Dr Gregory finds himself in agreement with Professor J. H. MCGREGORY—an authority on fossil man and a colleague of Dr Osborn. Seeing that our conception of man's near relationship to the anthropoid apes is based largely on the structural resemblance of his brain to theirs, there was lively speculation as to whether Dr Tilney would take the side of Osborn or of Gregory in this dispute. So well does Dr Tilney hide his hand that it is not until almost the last page is reached that the reader discovers which has won his favour. On page 1043 we read: "We are wise if we turn our attention not to these simians, but rather to the generalized mammalian ancestors from which both apes and man took origin to that stock which may be traced, as Huxley and others maintain, to the organization of some lowly mammal such as the tree-shrew."

To those who have plodded through the evidence which Dr Tilney has adduced in the previous thousand richly illustrated pages his final judgement comes with a shock of surprise. His verdict does not reflect the evidence. Let us summarize the nature of Dr Tilney's evidence. He has taken carefully preserved brains of eleven primate animals—namely, the lemur, tarsius, marmoset, howler, monkey, baboon, macaque, gibbon, orang, chimpanzee, gorilla, and man—in ascending series, and cut them into serial sections. The sections which he figures and describes begin at the lower end of the medulla oblongata and end where the peduncles of the brain merge in the great basal ganglia—the corpus striatum and optic thalamus. Of these great and important masses he gives no account, nor does he deal with the most prominent of all the elements which enter into the formation of the primate brain—the cerebral cortex. All the important memoirs which have appeared in the present century on cortical areas of the brains of man and ape are left out of account. Dr Tilney has stationed himself at the great gateway to the brain—its basal stem—and noted more carefully than anyone has yet done the highways which carry the chief tides of communications to and from the brain, and the relays of grey matters scattered along these highways. He figures the graded rise of the pyramidal system as one ascends from the marmoset to man—showing a growing domination of the cerebral cortex over the motor centres of the spinal axis, he traces a corresponding rise in the great afferent tracts which pour messages from

¹ *The Brain from Ape to Man*. By Frederick Tilney. Ph.D. M.D. With chapters on the Reconstruction of the Cray Matter in the Primate Brain. Stem by Henry Alsop Riley. A.M. M.D. Foreword by Henry Fairfield Osborn. Sc.D. F.L.S. London: H. K. Lewis and Co. Ltd. 1923. In two volumes. (8 x 11 in.) 3120 557 illustrations many in colour 45 5s net the two volumes.)

the body into the basal stations of the brain stem. More especially has his attention been directed to stations and tracts concerned with cerebellar functions—the lower olive, the dentate nucleus, the red nucleus, and the putative grey matter. Here again Dr Tilney finds a graded series, the condition seen in the human brain is but the culmination of an evolutionary or developmental movement which has all its beginnings fully displayed in the brain of the marmoset. And yet this fact remains, which Dr Tilney himself points out, the big steps do not occur in passing from the great anthropoid to man, but in going from the lower ape to the maulike ape. The cerebellar organization of the gorilla stands much closer to that of man than it does to that of the baboon. It will be seen thus that Dr Tilney's evidence—that is, the facts on which he bases his final verdict—is drawn from an important but very restricted field of observation. All the rest of the body, save the brain stem, is left out of account.

His long and laborious investigation of the basal parts of the brain has made a deep impression on Dr Tilney's outlook on evolutionary problems. The samples he examined represent the state of cerebral elaboration in all forms of primate animals, from the lowest to the highest, and in all of them he found processes at work which tend towards a common goal—the bringing of the lower centres under the control of the cerebral cortex—a process to which Dr Tilney gives the term "neokinesis." The difference between the marmoset and man depends on the degree to which neokinesis has succeeded. On this matter it is best, perhaps, to let Dr Tilney speak for himself.

But these facts, correlated here perhaps for the first time and standing alone without the aid of commentary or special interpretation, speak in no uncertain terms of a structural unfolding in the brain of primates whose evolutionary significance may be seen in the progressive extension of their behavioral capacities. In this aspect these factors may appear merely as a conventional summation of scientific deductions. They may fail entirely to create an impression of the actual *dynamic force* which has behind them.

The reviewer has italicized "dynamic force" because it is the power to which Dr Tilney appeals when he desires to give an explanation of what he has found. Can a biologist visualize the power which Dr Tilney postulates to explain the organization of the brain of man and ape? We know very little, so far, as to how the behaviour of developing nerve cells is regulated, the researches of Dr Happers and of others reveal the power of neuroblasts to move their position and also to alter their arrangements. If Dr Tilney means by "dynamic force" the capacity of developing nerve cells to behave in a certain way, then we can visualize his meaning. But the behaviour of any group of nerve cells depends on their inheritance. When we find the nerve cells which go to form the olivary body behaving in a similar way in all primates we account for this in a common manner of behaviour by supposing a common inheritance which has come from a simple form lying at the very base of the primate stem of evolution. But when we find these olivary neuroblasts behaving in man and the gorilla in almost an identical manner we explain their particular agreement, and at the same time their difference from all representatives of the lower primates, by a much later separation of their evolutionary lines of descent. In support of such a conclusion evidence could be cited from hundreds of other structures which the gorilla and man have in common. Man and the great anthropoids are partakers not only in the general primate inheritance but in a particular share of that inheritance.

It would be unjust to Dr Tilney and to the publishers of this truly magnificent book to permit this review to conclude on a note of criticism. The author has striven successfully to serve expert anatomists by supplying them with masses of fact of which they stood in need, he has sought to meet the needs of inexpert readers by supplying them with clearly expressed general conclusions and with faithful illustrations, often beautifully reproduced, of the structures which form the subject-matter of his text. The publishers have spared no expense in making the book attractive. Neurologists and anthropologists will be indebted to Dr Tilney's labours for many years to come.

OCCUPATIONAL SKIN DISEASES

WE welcome the third edition of Dr PROSSER WHITE's well-known work on occupational diseases of the skin. It has now become a veritable encyclopædia on all forms of skin disease in any way associated with industrial activities, whether actually caused by the industry or not, and the author has even included burns caused by heat, electricity, and x rays, and also frost-bite. Not only has Dr Prosser White given us the benefit of his own very extensive experience in this field, but he has collected and collated all the scattered observations and experiments of every other worker. The result is a most valuable compilation. It is not only valuable to our own profession, but also to all those who are interested in the welfare of the industrial community and to those members of the legal profession who are increasingly concerned with questions of compensation for injury or disease arising in the course of employment—questions open to serious debate, for it is often a matter of great difficulty to determine whether the employment is in any way responsible. One industrial complaint which has lately been much under discussion in this country is the so-called "baker's eczema." It will be remembered that quite recently the workmen's organizations have done their best to alarm the public by stories of the risks run by bakers of contracting this disease. Dr Prosser White has come to the conclusion that eruptions caused certainly not solely by the materials handled by bakers in their trade are exceptional, and Etern, a German writer, is even more definitely of the same opinion. But as long as workers can obtain compensation for industrial dermatitis it is likely to remain common.

The author's remarks on sensitization—namely, heightened hyperæsthesia towards certain irritants—are interesting. He has formed the opinion that with the industrial inorganic chemical irritants sensitization is rare. Whatever the nature of the eruption, it is always due to direct physical, chemical, or mechanical injury or irritation. He states that if the eruption persists continuously or repeats itself when the offending substance is completely withdrawn, it should be inferred that the original agent is not the cause. But no doubt he finds it difficult to persuade the courts to take this view. Insurance records could provide scores of cases of patients drawing compensation allowances for dermatitis months after all contact with the original irritant. The importance of the whole subject is shown by the figures provided by various dermatologists. In some clinics the percentage of occupational diseases amounts to as much as 20 per cent of all the cases seen. At the lowest computation there are in Great Britain between 18,000 and 19,000 new cases of skin diseases due to occupation every year. The employers' liability insurance companies can testify to the loss entailed thereby.

While we have nothing but praise for the industry and thoroughness devoted to the production of this book, we feel bound to point out that it possesses some irritating features—one of these is the excessive use of heavy type and italics in the text. The unnecessary employment of italics in places where no emphasis is called for reminds us of Topsy's communications to *Punch*. Dr Prosser White is also fond of coming new additions to dermatological terminology, and the worst of these is the terrible word used by him as the main title of his book. "Dermatogoses" merits all the strictures that have ever been passed by scholars on medical nomenclature. This word is supposed to mean skin diseases caused by work. If he feels compelled to translate "occupational diseases of the skin" into Greek, the word "ergodermatoses," although nothing to be proud of, would at least do less violence to the rules of grammar. Having registered this protest we have only to add that the photographs are excellent and excellently reproduced, and that the generous and complete index (occupying over two hundred pages) is one of the best things in the book.

214 *Dermatogoses or Occupational Affections of the Skin*. By R. Prosser White, M.D., F.R.C.S. Third edition. London: H. K. Lewis and Co. Ltd. 1928. (Demy 8vo 1p 21 x 7 3/4. 58 figures on 52 plates. 35s. net.)

PROGRESS IN OBSTETRICS AND GYNAECOLOGY

ONE of the essentials in a series of works dealing with 'recent advances' in any branch of medicine is that the books should be brought out at reasonably short intervals. We are glad to see that this is being kept in mind in the case of Dr Bourne's excellent little book *Recent Advances in Obstetrics and Gynaecology*.² Very little need be said to introduce this second edition, for we imagine that almost all those who are specially interested in the subjects are already familiar with the first edition. But if there be any such who are not in this position, then we cordially recommend it to their immediate notice. Briefly the book is a short and lucid review of the results of research, both scientific and clinical, which have marked definite progress in obstetrics and gynaecology in recent years. In the case of obstetrics, for example, pride of place is very properly given to the subject of ante-natal care and to a study of the difficult question of maternal mortality. The causation of stillbirth, the chemistry of the blood and urine in pregnancy, the haemorrhages, the treatment of eclampsia, Caesarian section, and puerperal sepsis are the headings of the other chapters and sufficiently indicate the scope of the work. In the second part, which is devoted to gynaecology, the recent methods of investigating and dealing with sterility and with prolapse are discussed. The newer work on endometrial and the use of x-rays, electrotherapeutics, and radium are all admirably discussed. In this second edition an interesting chapter has been added on the ovarian hormones, which summarizes very judiciously the present position of this most interesting branch of research, and at the same time indicates the prospects which it opens out in regard to gynaecological therapy.

We congratulate Dr Bourne on the success of his book, which ought, unquestionably, to find its way into the library of everyone who is engaged in obstetrical and gynaecological work.

FERMENT ACTION

THE first two parts of *Die Methoden der Fermente*³ (Methods of Ferment Investigation) were reviewed in our issue of March 17th (p. 454). Three more parts have now appeared, and these complete the volume, which altogether contains about 1,600 pages. The majority of contributors are German, but there are articles from other countries by such well-known authorities as Fenger, Thunberg, Hopkins, Harden, and Newton Harvey. The articles are of a high average standard, and the following are some that appear to deserve special mention.

The first division of the book, which deals with general methods, is concluded by two valuable articles. A full account of Warburg's methods of measuring tissue respiration is given by Dr Krieb, a worker in his laboratory, and Dr Blaschko, one of Meyerhof's assistants, contributes an article on microcalorimetry. These articles are of particular interest because they come from the laboratories in which have been developed these new methods that are assuming more and more importance. The second division of the book deals with special methods for the investigation of the different classes of ferments—for example, saccharase, maltase, and nuclease. Most of these articles deal with highly specialized problems, but some are of wider interest. Thunberg describes the measurement of oxygen acceptors and gives a full description of his methylene-blue method. Sir F. Gowland Hopkins contributes a short article on the important subject of glutathione. Schmidt, of Limben's laboratory at Frankfurt, writes an article of twenty-five pages on lactacogenin. A. Harden contributes a short article on yeast zymase. Lohmann, of Meyerhof's laboratory, gives an account of the chemical determination of glycolysis and the resynthesis of carbohydrate. Newton

Harvey of Princeton gives a short account of work on luciferase. The third division of the book deals first with the demonstration of ferments in biological material, such as plant cells, animal tissue, and milk, and secondly, with methods for measuring the action of ferments of clinical interest. This latter portion is condensed into seventy pages, in it are described the chief methods for studying the ferments of the stomach and pancreas, and the anti-proteolytic action of serum.

The fact that the volume under review contains 1,600 pages devoted to the description of methods used to measure ferment action is a striking proof of the magnitude of the science of biochemistry. The size of the work has, however, been enlarged to a somewhat unnecessary degree by inclusion of articles dealing with subjects that are not strictly ferment actions. For example, one article describes the biological methods for standardizing insulin. The inclusion of articles that are not strictly relevant in works of this nature is very undesirable for the following reasons. It is nowadays impossible to follow the periodical scientific literature in more than a very restricted field, and hence scientific workers are forced to rely more and more on encyclopaedic works such as the volume under review. There is a tendency for even these works to swell to unmanageable dimensions, and their value depends very largely on the care with which they are edited, for if swollen unduly by the inclusion of extraneous matter they lose much of their value. In fairness to the volume under review it must be said that it errs in this respect less than many other of the encyclopaedic works on biochemistry that have recently been produced in Germany.

HOMONYMOUS HEMIANOPIA

IN his monograph on homonymous hemianopia⁴ Dr F. Bunge working in the ophthalmological clinic of Kiel has collected a series of fifty-two cases showing this symptom, and recorded his findings. He has divided them according to the site of the lesion into two groups—that in which the optic tract or external geniculate body is involved, and that in which the lesion is supranuclear. The former group of eighteen cases is characterized by the retention of the hemianopic pupillary response in all myosis and narrowing of the contralateral palpebral aperture (Behr's phenomenon) in half of the cases. In four cases the loss was only incompletely hemianopic. Of the other fourteen cases in which it was complete, there was sparing of the macular region in six cases and a completely vertical line of division through the fixation point in eight. Among twenty-nine cases of supranuclear lesion interruption of the visual apparatus there was a lesion of the occipital cortex in twenty-five, of the central nuclei in two and of the internal capsule in two others. Of these twenty-five cases of lesions of the occipital cortex six showed the blind field to be limited by a vertical line through the fixation point, while in eighteen it was encroached upon by a circle of macular sparing extending from five to ten degrees around this point. This sparing of macular vision the author explains by a greater resistance of the more essential macular fibres, not containing the view which attributes it to the double vascular supply of the extreme occipital cortical pole.

NOTES ON BOOKS

BOOKS and articles from the pen of Professor LAZER HARRIS appear with dazzling frequency. His new book *The ABC of Verres*⁵ is true to its title: it gives in a popular form the essential facts about the nervous system, its anatomy and physiology. Of special value is the emphasis it lays throughout on the use of the experimental method in establishing our knowledge of the working of the nervous system. In view of the statement repeatedly made that Sir Charles Bell discovered the function of the nerve roots without resort to animal experiment the quotation from Bell's pamphlet 'An Idea of a New Anatomy of the Brain' printed in 1811 to the effect that

² *Recent Advances in Obstetrics and Gynaecology*. By Aleck W. Bourne. M.D. B.Ch. Camb. F.R.C.S. Eng. Second edition. London J. & A. Churchill, 1928. (5 x 8½ pp. x + 382, 67 figures, 12s. 6d. net.)

³ *Die Fermente und ihre Wirkungen*. Von Professor Carl Oppenheimer. Fünfte völlig neu bearbeitete Auflage. Band III. *Die Methodik der Fermente*. Unter Mitarbeit von Fachgenossen. Herausgegeben von Carl Oppenheimer und Ludwig Pincus. Lieferung III. 14 und 15. Leipzig G. Thieme, 1928. (72 x 10½ Lieferung III, pp. 625-944, 45 figures, 15s. 6d. net. Lieferung IV, pp. 945-1264, 59 figures, Lieferung V, pp. 1265-1578, 57 figures. Each part 12s.)

⁴ *Über Homonyme Hemianopsie*. Von E. Bunge. Berlin S. Karger, 1928. (Sup. roy. 8vo pp. 51, 1 plate, M.2.80.)

⁵ *The ABC of Verres*. By Dr F. Lazer Harris. M.D. D.Sc. London Egan Paul Trench Trubner and Co. Ltd. 1928. (Cr. 8vo pp. ix + 223, 14 figures, 4s. 6d. net.)

only after such an experiment did the meaning of the double connection of the nerves with the spinal cord become clear to him, is of particular interest. The account of Pavlov's work, though good, is brief, and might well be expanded in a later edition. The diagrams are clear and adequately explanatory of the well written text.

The question of propaganda in health matters is much before the medical profession at the present time, and a contribution by two experts is welcome. Dr CLAUDE LILLINGSTON and Miss NORAH HILL, who jointly edit *The World's Health*, have collected nearly forty articles in a volume entitled *How to Enjoy Health*, and it may be said at once that they are very good examples of their kind. Each article is by one of the authors, is indicated by initials, but in each case the work has been checked by both so that what is called 'technicalities and scientific jargon' has been censured by Miss Hill, while all facts have been verified by Dr Lillingston. The result is clarity, accuracy, freedom from fads and personal prejudices, a pleasant style, and an interest which should arrest any reader's attention and keep it fixed. 'The business girl's day' is a typical example, the daily life of Gertrude, from her 'bachelor' quarters in the suburbs of a large town to her seat in the far corner of the office and so home again to bed, is faithfully described with intelligent counsel for its betterment. On 'constipation, the common cold, or the medical aspects of tobacco,' Dr Lillingston shows how a controversial subject may be presented to the public without bias and yet with definite conclusions, while on 'whooping cough' Miss Hill shows how facts may be set out so as to state an unanswerable case for an improvement in preventive measures. It is stated that these articles have been translated into various languages, and some have already appeared in many different Red Cross journals. They are worthy of careful study by medical officers of health and others concerned with health propaganda.

The treatise on the problems of the ties* by Drs J WILDER and J SILBERMAN of the Maria Theresa Schloss Institute for Nervous Diseases at Vienna, is the first monograph on the subject since the classical work of Meigs and Feindel. It is based on the study of 370 cases of ties of various kinds observed between the years 1914 and 1926. The work is divided into three parts. In the first, which is entitled 'The modern view of the problem of the ties, with special reference to stunted hyperkineses' Dr Wilder discusses the varieties of ties, particularly ties in children and war tie of which 213 cases were observed in the period 1914-18, then pathogenesis, nosology and treatment. The second part, written by Dr Wilder in collaboration with Dr Silbermann, contains the histories of 57 cases of organic and functional ties, 17 of which have been abstracted from the literature and 40 are original. The third part contains a short description of a case of Gilles de la Tourette's disease.

The specialist, the general practitioner, and the medical student have all been liberally treated in the matter of manuals on venereal diseases. Mr TURNER WARWICK, in his *Handbook on Venereal Diseases*,² has catered entirely for nurses who up to the present have had to search for any information they may desire among textbooks whose wealth of technical details renders them inconvenient foundations to knowledge. In the numerous venereal disease clinics scattered throughout the country there are working many nurses and orderlies who will welcome the opportunity Mr Warwick has provided for their obtaining information concerning the general principles that underlie the diagnosis and treatment of venereal disease. Moreover, this book deals not only with the clinical side of the subject, but also with questions that concern public health, and should do much to enlist the aid of nurses and orderlies in the fight against venereal disease.

Dr JORDAN'S *Text Book of General Bacteriology*¹⁰ is a favourite book for students in America, and has had many readers in this country in the years that have passed since its first publication in 1908. We have now received the ninth edition and notice that it is a little larger than its predecessors, that the chapter on the parasitic protozoa has been entirely rewritten and that new material has been added on the bacteriology of scarlet fever, erysipelas, and rheumatic fever. Otherwise the book has the same appearance and arrangement as before.

How to Enjoy Health. By Claude Lillingston M.D. and Norah Hill A.R.C.N. With a preface by Sir Squire Sprigge M.D. London: Hodder and Stoughton, 1928. (4 x 7 1/2 pp. 287 2/- net.)
Handbook on Venereal Diseases. By Dr J. Wilder and Dr J. Silbermann B.M.S. 3 Kaizer (Sup. pp. 8vo pp. 100 2 figures 1/3 4d.)

PREPARATIONS AND APPLIANCES.

A FORCEPS FOR INTRAUTERINE APPLICATIONS.

Mr H. J. McCURRICIE M.S. F.R.C.S. (Hove), writes: The application of glycine to the interior of the uterus advocated by Remington Hobbs for the treatment of infections of the endometrium, has in my experience, yielded excellent results both in the puerperal and the non-puerperal types of infection. The apparatus described by him, however, has always struck me as being rather difficult to use. Owing to the introducer being straight the surgeon's hand obstructs his view and the blades of the forceps are so arranged that in withdrawing the forceps they may catch the catheter and withdraw it also. The catch I found a nuisance as it was sometimes difficult to release without disturbing the catheter, and its presence made it more difficult to 'feed in' the catheter. The Sims speculum and the Hobbs anterior vaginal speculum require holding by an assistant, whose hands may get in the way. I therefore designed the introducing forceps illustrated here. It is so arranged that the surgeon's hand does not hide the cervix or the tip of the catheter. In ante flexion the catheter is passed under the forceps and its tip brought up between the blades so as to point anteriorly, in retro flexion the catheter is passed along the top of the forceps and its tip lowered between the blades so as to point backwards. There is no catch, and the blades are not grooved. The instrument makes an excellent swab holder. I use a Cusco's bivalve vaginal speculum which obviates the need for an assistant and thereby removes a further obstacle to the view. The external os is dried by wool held in this forceps. Clean wool is picked up and applied to the cervix and the soiled wool then dropped in a receptacle. This process is repeated until the outside of the cervix is clean, then, without changing hands the forceps is used to pick up and introduce and propel the catheter into the uterus. I usually have the patient in the lithotomy position or in the gynaecological modification of that position (that is feet lower than in the lithotomy position) but the Sims position would be nearly as good. The catheter contains air until the glycerine passes through it, and some air will be expelled into the uterus but this does not matter at all. It would of course be possible to fill the catheter with glycerine first but this seems to me to be unnecessary. I suggest that the method described here will considerably simplify the process of applying this most satisfactory form of treatment.

The instrument was made for me by Messrs. Down Bros., Ltd.

NEW GLAXO

'Prescription (humanised) Glaxo' is a new preparation of this well known infants' food in which a full content of vitamin D has been ensured by the addition of ostein.

The makers point out that in the past there was a tendency to recommend a high content of fat in infants' food because only by this means could an adequate supply of the antirachitic vitamin be ensured. This high fat feeding however defeated its own object because the excess fat hindered the absorption of calcium by forming insoluble calcium soaps. The provision of an adequate supply of vitamin D by the addition of a vitamin concentrate such as ostein avoids this difficulty and also avoids the production of digestive disturbances that frequently are caused by excess of fat.

The analysis provided by the makers is as follows:

	Dry powder	Reconstituted 1 in 8.
Fat	20.0	2.5
Proteins .. .	17.0	2.1
Lactose .. .	56.0	7.0
Ash .. .	5.0	0.6
Moisture .. .	2.0	0.7
	100.0	100.0

The reconstituted milk is therefore very similar to human milk in its percentage composition.

A SPIRIT PROOF SYRINGE CASE

We have received from the Security Druggist & Sundries Company (23 Grosvenor Gardens, South Hampstead N.W.6) their patent Masse hypodermic syringe carrier fitted with a hypodermic syringe and a serum syringe and needles. The instruments when not in use are attached to a plate which fits into a metal case containing methylated spirit. The carrier has a patent foot mount, which enables it to stand upright securely. It is easily opened, and the syringe and needle can be quickly withdrawn and replaced in the fluid. The specimen supplied to us proved to be perfectly spirit tight in all positions and the apparatus is likely to be a very popular addition to the general practitioner's bag since its contents can be kept sterile. The price of the complete outfit with syringes is 17s. 6d. the patent case with the plate but without the syringes can be supplied for 8s. 6d.

STANIFORM

Staniform is methyl stannic iodide and the manufacturers (Whiffen and Sons Ltd. Loudon S.W.6) claim that it combines the well known usefulness of the staphylococcal infection with the powerful germicidal properties of iodine and that it is indicated generally for use in local inflammations such as boils, ulcers, chafed skin etc. The drug is supplied as an ointment, and also as a dusting powder.

ON THE TREATMENT OF FRACTURES A PROBLEM OF ORGANIZATION

BY

ERNST W. HEY CROVIS, M.D., M.S., F.R.C.S.,
PROFESSOR OF SURGERY TO THE UNIVERSITY OF BRISTOL

On the Acquisition and Application of Knowledge

IN the forward march of human progress it is the pioneer, or discoverer of new paths and fresh territory, who holds the public eye and captures the popular imagination. But if the new discovery is to be of any lasting value the pioneer must be followed by an organized band of workers who colonize and cultivate the new territory, whether this be actual land or a mere domain of knowledge. Quite rightly we shall always regard Columbus and Cabot as amongst the greatest of the world's heroes, but the practical value of their heroism would have been wasted if successive generations of seamen, engineers, and colonists had not established an easy and safe route to the New World and developed its resources. Thus it is, too, in matters of applied science—it is only given to the fortunate few to acquire new knowledge, but it is the duty of those who come after to see that this new knowledge is applied.

There is no doubt some danger at present in medical science of the attention being so concentrated on the quest for new knowledge of hidden mysteries that the patient and systematic application of knowledge already in our possession about everyday ailments may be neglected. It is quite right that ceaseless work should be expended on trying to discover the cause and cure of cancer, but we must nevertheless remind ourselves and instruct the public that the causation and treatment of tuberculosis are known and that we ought to apply knowledge already in our possession at the same time that quests for new knowledge are being organized.

For the moment, however, I wish to discuss a problem which is even simpler than that of tuberculosis—namely, the treatment of fractures.

In this matter it may be well to begin by considering the conditions and lessons of the late war. There was no great medical problem at the beginning of the war which seemed so hopeless as that of the treatment of gunshot fractures, and there was certainly none which by the end of the war was so satisfactorily solved. And yet, when we come to ask, "To what discovery was this happy result due?" we are forced to admit that there was no new thing found but that the whole progress was due to organization, team work, and the training of workers. It was not the acquisition of new knowledge, but the application of well-established principles which turned failure into success. As far as I know, there was no new discovery made about the treatment of fractures during the war. The importance of early excision of infected wounds was established, and this seemed to be more important than any of the chemical disinfectants—hypochlorates, hypertonic salt, bipp, or flavine—each of which proved useful, but could not be claimed as essentially new. Probably the Carrel-Dakin treatment, combining mechanical with chemical cleansing, was the nearest approach to a new discovery in the realm of fracture treatment.

On the other hand, progress was definitely hindered by what at that time was a comparatively new method—namely, the plating of fractures—and many limbs were lost or ruined before this was finally set aside. Success in fracture treatment during the war was achieved by organization, team work, the training of new men and the segregation of difficult cases in special hospitals; this success was made possible by the fact that the general control of fracture treatment was entrusted to one (our own revered emeritus president) whose unrivalled know-

ledge of how to treat fractures was only equalled by his wonderful capacity for knowing how to deal with men—both men above him, in brass hats, and the men below him in hide-bound traditions.

I think that we are all convinced that the fracture problem of to-day is one like that of the war, in that it requires not new knowledge, but the organized application of the knowledge we already possess. It requires the segregation of cases, the training of team workers, and the systematic tabulation of results. We want not merely a collection of *slav* records, but an accurate knowledge of functional results.

The Arguments for Reform

Before discussing the details of reorganization of the teaching and practice of fractures it may fairly be asked: What evidence exists that such reform is necessary? Naturally the first argument which springs to the mind is the very great number of bad fracture results which are constantly met with in practice. The stiff shoulder-joints with the arm tied to the side, the fixed elbow-joint, the pronated hand, the unreduced Colles's fracture, the ununited neck of the femur, the short leg, the crooked shin, and the everted backwardly displaced foot—these are conditions which we are consulted about perhaps once or twice every week, and in nearly all we are oppressed with the thought that prevention of such deformities would have been easy, but that complete cure is almost impossible. In the great majority of these cases the original fault has been a matter of neglect or oversight. Either the patient has been in a large hospital where in the press of work he has been relegated to the care of a junior resident and hurried out at the earliest possible moment, or he may have been in a small country hospital, where he was splinted and made comfortable for the time being in the happy belief that if he did not make a good recovery he could be transferred elsewhere later on for "orthopaedic treatment", in a small minority of cases the fault has been that of attempting too much. An open or a comminuted fracture has seemed to call for operative treatment, and this has been undertaken without the experience and training which are necessary to justify such.

The mere collection and review of any series of bad fracture results must, then, lead to the question as to frequency of such disasters, and whether it is sufficiently great to justify a demand for reorganization of the fracture service. And here we are at once faced with what in itself constitutes a strong reason for reform—namely, the absence of any systematic records of after-results. We really do not know what proportion of cases of broken limbs leads to permanent or to partial incapacity. And yet from an economic or industrial point of view this is surely important information which we ought to be able to get. Does there exist in this country a single hospital or fracture service which collects and tabulates the results of its fracture cases one year after the injury? Such information would be invaluable, both for noting the type of injury which gives the worst final result, and especially as a standard of comparison with which new methods and organization could be compared.

We certainly know that in most places including the majority of the teaching and municipal hospitals and all the small hospitals, there is no attempt at organization of the immediate or the after treatment of fractures. There is no segregation, or team work, or systematic following up of cases. In fact, all those features of organization which the war taught us to value are conspicuous by their absence in modern civil practice.

There is, then, ample evidence of the need for improvement in the fracture service of this country and we shall be justified in considering how this improvement may best be brought about in relation to different types of hospital and in general practice.

The Teaching Hospitals

The university teaching hospital is usually one which contains about 300 to 500 beds, and it has long been obvious that the right policy to be adopted there is the

provision of a fracture department of a suitable size to deal with in-patient and out-patient fracture cases. The actual number of beds to be set aside for fracture work would probably be about 10 per cent of the whole. It would be unnecessary and undesirable to make any rule that all fracture cases must go to the fracture wards. The department would be there, and the cases would go there naturally if the work was well done. The very great majority of general surgeons would be only too glad to rid their wards of fractures, although they might wish occasionally to keep some special case in their own hands.

The personnel responsible for the fracture department would consist of a surgeon, an assistant, a resident, sisters, an officer in charge of the physiotherapy, and the massage staff. In addition to these there ought to be a registrar, with sufficient clerical staff to carry out a regular tabulation of results with a good follow-up system. Every student would have to act as a dresser for two or three months, and during this time he would see both the in-patient and out-patient work, he would assist in putting up fractures in the first place, and he would see the after-treatment and the late results. This is, of course, no novel plan. Its adoption has been urged ever since the war. The reasons in its favour are convincing, while the arguments against it are so weak that it really no longer presents a debatable proposition. By providing a department the very *raison d'être* of which is the study, treatment and cure of fractures, each patient admitted to the department would be assured of the best possible chances of a speedy recovery. On the other hand, in many of the teaching hospitals now the beds are overcrowded, the fracture cases are regarded as a nuisance to be dealt with by a resident, who himself is probably more interested in abdominal work, and whose chief aim is to avoid blocking the beds with fractures. If, in spite of his vigilance, a fracture case is admitted, his next aim is to shift it as quickly as possible to the limbo of a general out-patient department or to a Poor Law hospital. Very naturally, then, if a fracture has been put up in plaster or other splint in a teaching hospital and then sent on to a Poor Law hospital, the medical officer at the latter institution, who is overburdened with routine work, will be content to carry on without himself making any critical examination or initiating any fresh treatment.

The present education of the student, too, is most unsatisfactory in relation to fractures, he often never sees any treated except in the casualty department, and then only for a brief moment. More often his experience of fractures includes seeing some difficult case operated upon while the more ordinary valid cases are wrapped up and got rid of. No wonder that when he comes to practise himself he carries out the same ideas—that is, if he is cautious, he always contents himself with giving some sort of rough and ready first aid, and then tries to find out how he can send the patient away to someone else. If he is adventurous and the patient is a suitable one, he will suggest doing an open operation, and provides himself with some plates and screws for the purpose.

If the argument for a special fracture department is so strong at every teaching hospital, if it will improve the quality of the treatment and expedite the patient's recovery, if it will improve the teaching of students and train practitioners to know this part of their work—then we may well ask why this reform has not been adopted long ago in all our chief institutions. The reasons must be of an obscure character, because they have never been put into plain words by those who deprecate any change. Probably reluctance on the part of the surgical staff to specialize in fracture treatment, together with a shortage of beds, are the two main factors which tend to block progress, but in this respect there is a very definite indication of a steady change in the right direction. Many of the teaching hospitals have now got either a fracture ward or else an orthopaedic department to which fractures are sent. In most cases the number of beds available for fractures is wholly inadequate, but this is being generally remedied. I would like to emphasize this one point very strongly, most hospitals now have 10 to 15 per cent of their beds occupied by fractures, and it will not necessitate

any provision of fresh beds if this 10 per cent of the cases be put together in the same wards instead of being scattered about all over the hospital.

Municipal Hospitals

It is quite clear, however, that the teaching hospital, together with the other large voluntary hospitals, cannot deal with all fracture cases or even all of those of a serious character—for example, fractured spine, pelvis, femur, and tibia. At any rate, the voluntary hospitals cannot keep such cases for the full period necessary for functional recovery. Under existing arrangements one of two things happens. Either the bad case is refused admission to the overcrowded voluntary hospital and is sent direct to the municipal hospital, or, more commonly, it is first taken to the voluntary hospital, and then, after a few weeks, it is transferred to the municipal hospital. Sooner or later, therefore, the municipal hospital must take over many serious cases of fracture, and these will, of course, be just those which require the greatest care and skill in their treatment. The majority of municipal hospitals are, however, very much understaffed. For example, a municipal or Poor Law hospital of 500 or 600 beds often only has four whole-time medical officers and four visiting consultants—a total staff of eight, as compared with the twenty-five or thirty men who are on the staff of a voluntary hospital of the same size. In these circumstances it is almost impossible for fracture cases to receive anything but the most perfunctory treatment, and usually this is only of an expectant character. The remedy for this state of affairs is not difficult to suggest, but very difficult to carry out.

In the first place there ought to be a definite co-operation between the voluntary and municipal hospitals. Whatever else this includes it should certainly imply an active liaison between the staffs of the two types of institution. The surgical staff in charge of the fractures at the voluntary hospital should be consulting surgeons to the municipal hospital, and should superintend the work at both places. It will then be a matter of local circumstances whether bad fractures first go to the voluntary hospital and are later transferred to the municipal hospital, or whether from the outset certain types of fracture—for example, those of the femoral neck, pelvis, or spine—should from the outset go to the municipal hospital. The main and essential point is that in every city and large country town there should be secured a single fracture service for working-class patients. This would be carried out by a team of men working under a single chief, and the work would be partly done at the voluntary or teaching hospital and partly at the Poor Law or municipal institution. At the latter place there should be full provision for functional after-treatment—curative workshops where men during their recovery could be kept usefully employed, instead of drifting into that hopeless condition of compensation neurosis which awaits so many who are sent home with nothing to do. In any case such a man is a charge on the community during his invalidity, and it would really be much more economical to keep him at an institution where he is trained to resume work than to allow him to become a waste.

The Smaller Hospitals

The problem of fracture treatment at the smaller hospitals in country towns is becoming more important every day, because of the large number of motor accidents which occur almost at their doors, and in the country hospitals there is a definite selective influence by which only the worst cases remain for treatment. The injured person is usually far from home, and his own wish is to be removed to an institution near his home. This may be effected after treatment has been given. Therefore a large proportion of the fractures in country hospitals are of a serious character. The character of these smaller hospitals, the extent of their equipment, and the work turned out by them varies very much in character. Some of them are modern and very well equipped, others are certainly bad, and if it were not for the protective halo of our cherished voluntary system they would be reformed or abolished.

Probably in the better type of country hospital the fracture work compares very favourably with that done in the teaching hospitals in the service of men not interested in fractures, but, on the other hand, there are many small hospitals where the treatment is very bad. This may be due to faults in the personnel or in the equipment, it is much easier to deal with the latter than the former. It should be generally conceded that, except as a temporary emergency, no serious cases of fracture should be admitted to a hospital which is not provided with an x-ray plant and a proper supply of splints and appliances. An elaborate aseptic operating theatre is certainly not necessary. The matter of personnel is one of great difficulty, chiefly because in the type of hospital in my mind—that of about twenty beds in a town with a population of two or three thousand—all the general practitioners are on the staff, and it is difficult for one or other to act as a specialist or consultant for the other.

Probably the easiest solution of the difficulty is the appointment of a resident house surgeon who has a good knowledge of fracture work. Such a man will be of invaluable assistance to the whole staff, who will be only too glad to let him carry out routine fracture treatment. Unfortunately a large number—and I would say the majority of recently qualified men—do not possess this requisite knowledge, or, rather, practical experience. This brings us back to the first part of my thesis—namely, that our teaching hospitals do not give a student enough practical fracture work to fit him for this part of his profession. If we are asked where a man could go to in this country to get a three months' intensive post-graduate training in the treatment of fractures, we should have to admit that there are very few such places. Now this is certainly a most serious indictment of our surgical educational system.

To return to the small hospital and its fractures. At present what happens at the less satisfactory of these institutions is that fractures are put up within the first few days of admission and then nothing further is done for perhaps six to eight weeks. If at the end of that time marked deformity is revealed when the bandages are removed, or the patient gets up, the case is sent off to a specialist at some teaching centre for further treatment. Such conditions as fracture of the neck of the humerus with bad position and a stiff joint, forearm bones with crossed union, an unreduced Colles's fracture, an ununited neck of the femur, a shaft of the femur with two or three inches overlapping, a malunited fracture of the tibia or an unreduced fracture-dislocation of the ankle are common instances of serious crippling deformities which would have been comparatively easy to deal with during the first few days after injury, but which are not only difficult after several months, but at that period can seldom be restored to full functional recovery. Every case of fracture in which reduction and good position has not been attained by the end of the second week ought to have further treatment other than mere *laissez-faire*, and in the case of the small hospitals some arrangement should be made by which a consultant's opinion can be called for without any loss of prestige on the part of the practitioner in charge. This might be arranged by the national health insurance authorities or else by the accident or compensation insurance companies in whose interests it surely is that these cases should be quickly and efficiently brought to recovery.

The Relation to the Insurance Companies

This opens up another point of view about the treatment of fractures. A man has a motor accident in which he sustains a fracture. If he is a better-class patient and is conscious after the accident, he is taken to his own doctor or to a nursing home and the cost of the treatment which he undergoes is ultimately borne by the insurance company. But if he is far from home or if he is a working man, he is taken to hospital and it usually happens that all professional attendance is given gratuitously, the insurance company merely paying for loss of time on the scale of the Workmen's Compensation Act. It frequently occurs that the gravity of the case is overlooked, and that

the fracture is put up in such deformity that the patient is either permanently crippled or else has to be sent to another institution for corrective treatment which seldom gives such a good result as if the case had been efficiently treated from the outset. Surely, as a mere matter of economy, it would pay the insurance societies, in which should be included the national health insurance authority, to safeguard themselves in this matter. This could be done to some extent by providing for the services of a consultant in all severe fracture cases soon after the accident, instead of delaying until a bad result is inevitable. Still better would it be if in all large centres of population good fracture clinics could be provided where the best treatment could be given in the first place and where after-care until the patient is restored to work would be provided. Such an institution is actually in existence in Madrid, and is supported partly by a Government grant, but chiefly by the insurance societies. It is very desirable that some of the chief insurance companies should be persuaded, as a first step in this direction, to draw up a table showing the number and classification of their fracture cases, the length of time taken for recovery and the cost of such cases during invalidity. I am confident that such a statistical inquiry would go a long way towards convincing the companies concerned that it would be in their own interests to help in the working out of some such scheme as has been suggested.

An Ambulance and X-Ray Service

As far as I have been able to learn many of the ambulance first-aid services have not modified their methods since the lessons of the war. In towns where accident patients have not far to be carried this is perhaps no great matter, but when fracture cases have to be transported for many miles over country roads we may well ask why it is that the Thomas splint is not used instead of the Liston. This point has been recently brought to my mind by a vigorous letter from my friend and fellow student Pearson, who writes urging this belated reform upon the overseas branch of the St John Ambulance. The essential nature of good x-ray work, both in the first diagnosis and also in the after-treatment of fractures is generally admitted and this equally important provision of a good ambulance service is also necessary. Both these things are to hand in all cities and large towns but they are often difficult to obtain in the country districts. Patients after an accident are frequently taken to their own homes, and sometimes—for example, in an injury to the hip-joint—it is not possible to be sure of the diagnosis without x-rays. It ought to be possible to provide a portable x-ray apparatus which could be taken to such patients and then if serious fracture is discovered, the same motor ambulance could, if necessary, move the injured man to the nearest suitable hospital. The provision of such a service should be a part of our national hospital system unfortunately, however, such a system does not exist, and the voluntary hospitals are overburdened already with the struggle for existence and have moreover no sense of responsibility for national schemes. The charge would therefore have to be made out of the country rates, supplemented by the insurance funds.

Conclusion

I am very sensible of the fact that I have been preaching to the converted, and that in the main I have only been saying what has been said so much better by our founder, Sir Robert Jones. But reforms do not come in a day and it is better to repeat what we know to be true than to remain silent because good advice is not acted upon immediately.

We know now how fractures ought to be treated, and that correct treatment will save personal disablement and economize loss. We know too, that organization, segregation, and team work are the essentials of good fracture work as much in peace time as in war. I have therefore thought it my duty in the high office you have conferred upon me to repeat these things you know so well, in the hope that we may be further stimulated to work for the much-needed reforms.

British Medical Journal.

SATURDAY, DECEMBER 1st, 1928

THE ASSOCIATION IN 1928

MEDICAL men and women owe it to themselves to give a few minutes thought every now and then to what is being done on their behalf and for the public good by the professional body which speaks in their name. Our present object is to offer them some material for consideration, but not to enter into details. An article of a few hundred words that tried to cover all the manifold activities of the British Medical Association during the past twelve months would make dull reading—it would be a mere catalogue, 'a plate of bones'. The full record of the year's work will appear next April in the Annual Report of Council, and in this brief survey we shall only point out some recent landmarks to those readers who are not as familiar as they might be with what goes on at the centre and at the periphery. By so doing we may perhaps give them also a better insight into the spirit and purpose of the great piece of living machinery known throughout the world as the B.M.A.

Speaking generally, it has been a year of consolidation and of progress along accustomed lines. There are no spectacular victories to record. Membership has grown by a thousand, and is now 34,500, so that in the past ten years there has been a total net gain of more than 14,000. Material resources expand with rising numbers, fresh activities open out, and new forms of service can be undertaken. When the centenary comes in 1932 the total ought to be 40,000 at least, for the field of recruitment is still large, and, unless we are mistaken in our judgement of the youth of to-day, the aims of the Association should make a special appeal to the generation of medical students who graduate during the next few years. Side by side with the growing membership there has been a steady growth of work at headquarters and a stirring of interest within the Divisions and Branches. From all parts of the country signs have come of vigorous life. We would not say that medical politics make a stronger appeal to the general body of members, but in the scientific and social spheres 1928 has seen a remarkable increase of local activity. Pages of our Supplement have been filled each week with notices of lectures, debates, demonstrations, and post graduate courses, or of dinners, dances, golf matches, and excursions. A debt of gratitude is surely owed to the honorary officers in town and country who give time and trouble to the task of bringing their neighbours together by such admirable means. We may note also as a healthy sign of the times the disposition among individual members to make personal contact with the Head Office, both by requests for information and advice on professional matters, and by their ever increasing use of the Association's Library, whose lending department has almost trebled its output in the last six years. Another means whereby members at the circumference can be brought into touch with the centre is the collective investigation of a clinical problem. Two very profitable inquiries of this kind have been set on foot this year by the Association, one into the treatment of

varicose ulceration, and the other into the after history of gastro-enterostomy cases. Useful information was also supplied by individual doctors in response to the questions drawn up by the Association's Committee on Puerperal Morbidity and Mortality when preparing its final report.

The leading event of the Association's year, its Annual Meeting at Cardiff under the presidency of Sir Evan Maclean, was an unqualified success—well planned, well attended, and thoroughly informative in the clinical and scientific part of its programme. In this latter respect our organization does notable work for medicine. Every summer it visits a medical centre, and becomes 'a gathering point of specialized minds' and a clearing house for new knowledge and new ideas, thus the Association fulfils one of its primary duties to the members at large. Our South African colleagues, following the lead of the parent body, held their first annual scientific meeting under the new constitution at Bloemfontein in March. Among many other services to medical science—apart from weekly publication of the *British Medical Journal* and periodical issue of two special journals—the Association at home has sent lecturers to Branches and Divisions throughout the country, and has added to the number of scholarships, prizes and grants which it awards for the encouragement of research and clinical observation. A beginning has also been made with a series of articles in the lay press intended to guide the public in matters of general health.

On the political side (using the word in its widest sense) much useful work has been done in committee and elsewhere. A conference was held in June to discuss contributory schemes for hospital benefit, and medical representatives of 200 voluntary hospitals in Great Britain and Ireland attended. The Insurance Acts Committee has kept guard over the interests of panel practitioners, and nothing that bears upon insurance medical practice—whether it be the revision of disciplinary procedure, or allegations in respect of excessive sickness claims, or a questionable phrase in the latest bill—has been allowed to go by default. In like manner a special committee is watching the scheme for local government reform now before Parliament, and two memorandums of evidence were submitted to the Royal Commission before it finally reported. The encroachments upon private practice by local authorities are under investigation by another special committee, whose interim report is now before the Divisions. One more document may be mentioned here—the Association's memorandum on noise in relation to the health of the community, which has aroused great public interest and widespread support in the newspapers. Lastly, among the visible (and audible) activities of 1928 at headquarters we must record the rapid progress made with extensions to the Association's building in Tavistock Square, and the enlargement of the Scottish House in Edinburgh.

So much for a single year's work. Of the position generally, it is true to say that no other vocational organization can be compared with the British Medical Association in respect of the scope and variety of its work, or its standing in the eyes of public authorities. It comprehends every aspect of professional life. Its conjoint aims are to advance the science and practice of medicine, to promote social intercourse among the members, to defend their interests, and to uphold professional standards. And beyond all these it stands for the public welfare. As Sir Robert Philip reminded us lately at the autumn Council dinner, this great organization a hundred years ago was simply a concept within the

brain cells of a young man. Charles Hastings did not seek material advantage; he had a spiritual inspiration. Ten years ago the British Medical Association, like every other institution, was suffering from the effects of a war unprecedented in scale and intensity. It has now far more than regained such ground as was lost, and is flourishing as never before. Nothing, however, could be worse than to end on a note of complacency, or to imply that material success, such as we see around us to day, is all that matters. Charles Hastings had an inspiration.

THE LOCAL GOVERNMENT BILL AND HEALTH ADMINISTRATION

In a leading article in the *Journal* of November 10th (p. 854), written before the Local Government Bill, 1928, was introduced in the House of Commons, we anticipated that the proposals of the Government would follow certain general lines, and the text of the bill shows that these anticipations were correct. The bill—that is, the measure applicable to England and Wales, but not to Scotland—is now under discussion in Parliament, and has been strongly attacked by both sections of the Opposition, as was to be expected, since it is the principal measure of the Government just prior to a general election. It is unfortunate that the concentration of attack mainly upon the financial aspects of the bill tends to divert attention from the very important provisions for the reform of local government machinery. It is only with these provisions so far as they affect health administration that the medical profession, as such, is concerned, and it may be said at once that broadly, they will have the support of the British Medical Association in so far as they are a step towards that unification of health administration which the Association has made its aim for so long. The whole object of any suggestions the Association has to offer is to make the bill a more effective instrument in securing the practical efficiency of health services. Some modifications of the bill seem essential if grave danger to these services, including the provision and management of hospitals, is to be avoided.

There are three aspects of the bill in its relation to health administration to which the attention of the medical profession will be mainly directed. One of these is its effect upon the position of medical officers of health and of Poor Law medical officers as regards their status, and then transfer, compensation and superannuation if their offices are disturbed. The provisions of the bill in this respect may be regarded as almost entirely satisfactory. The interests of existing officers are secured, and the clause relating to the expediting of the appointment of whole time medical officers of health, though it might with advantage be somewhat more specific as to the nature of the arrangements to be formulated, is clearly a great advance in the direction which the Association has for many years indicated as desirable. The Association will need, however, at a subsequent stage, to be watchful lest its general principle that whole time medical officers should not undertake domesticary practice is violated.

The second aspect of the bill in its relation to health matters concerns its main proposals for changes in administrative machinery with regard to both form and function. Here there is unfortunately room for some disappointment and need for early activity. Poor Law guardians, as such, are to be abolished,

and their functions transferred to the councils of counties and county boroughs, but there is no guarantee of that break up of the Poor Law, as it has been called, without which there will still be much overlapping and reduplication of provision of health and other services. The new authorities may, if they wish, give assistance under the Poor Law in respect alike of attention to health, of hospital accommodation, of educational provision, and of money, food, and shelter, as one miscellaneous whole and through one entirely new Public Assistance Committee, instead of attending to all health matters under the Public Health, Maternity and Child Welfare, Mental Deficiency, and other Acts through the appropriate committees, and to educational matters through the Education Committee, leaving only the more material and immediate relief to be continued by way of the Poor Law. Indeed, this conglomerate method of administration, which perpetuates most of the old evils and leads but a little way towards the unification of health services, appears rather to be encouraged by the bill, though permission is given to authorities to adopt the alternative and only satisfactory method. In the case of counties, too, which may contain large urban districts or boroughs, which are themselves satisfactorily conducting health services within their boundaries, the council of the county may proceed to establish and manage alternative health services covering the same areas or families, instead of being compelled to delegate to the councils of such county districts all functions similar to those which they are already administering with success. Further, though councils are to be permitted to place on their committees (even on the Public Health Committee, on which this has not hitherto been allowed) persons who are not members of the councils themselves, there is no guarantee that this will be done, so that there may very likely be committees dealing with the supply and management of hospitals on which there is no one who has any knowledge or experience of such work, or has any acquaintance with the opinions of hospital staffs and other interested practitioners.

As was stated in the leading article to which we have already referred, the British Medical Association regards it as highly important that these principles of distribution of functions, of delegation of functions, and of co-operation on committees should be made compulsory on authorities instead of merely permissive. A fourth principle previously mentioned as having been put forward by the Association was that a statutory local medical advisory committee should be established in each area. This matter is not dealt with in the bill in any way. In present circumstances it may be found desirable not to press for this, especially as a satisfactory alternative may be provided by Divisions of the Association being urged to secure more effective and constant co-operation with local councils in health matters.

The third aspect of the bill in relation to health administration is the effect which its financial provisions may have on the efficiency of health services. The system of block grants over quinquennial periods is to be substituted for annual grants in aid. Under this system it will be possible for a council if it wish, to spend but little money on health services and to divert the grant to say highways. At a time when many authorities have done little or even nothing, with regard to mentally deficient persons or to maternity or infant welfare—when, indeed, they have no statutory duty with regard to the latter except to set up a committee—this may in some areas lead to lamentable neglect. Further, the present power which

the Minister of Health has of withholding grant in cases of proved inefficiency will be abolished or is made by the bill so remote and conditioned as to be wholly ineffective. The education service is exempted from this allocation to the block grant and it has been suggested that certain of the health services should also be exempted for a limited period of years. It is at least true that there is grave danger to the needed development of such essential services unless this is done or unless the Minister secures to himself further controlling powers in this connexion. We rejoice that Mr Chamberlain, in his speech on the second reading of the bill, has undertaken that this matter shall receive sympathetic consideration.

THE KING'S ILLNESS

No calling has warmer feelings of loyalty to the Crown than the medical profession, and the sympathetic interest shown by members of the Royal Family in the progress of medicine and the relief of suffering has endeared them to us all. The King's illness, therefore is a matter of personal concern to our readers. They will have gathered some idea of the nature and course of the malady from the brief but expert bulletins, issued regularly since the evening of Wednesday November 21st, by Lord Dawson and Sir Stanley Hewitt who have throughout been in attendance upon His Majesty at Buckingham Palace.

The public nowadays expects to be taken into the doctors' confidence when the Sovereign is ill and to any observant medical eye the recent bulletins, though necessarily restrained, have been informative pointing to a serious infection such as must give rise to natural anxiety. His Majesty it appears, was not in his usual health on November 17th and began to suffer from what is called in homely speech a feverish cold. By November 21st there were definite signs of congestion in one lung with some pleurisy. With an increase of fever on November 24th the inflammation of the pleura tended to increase. By that time bacteriological tests had been made and the clinical diagnosis was confirmed by x-ray examination.

Doctors know well that an infection of this kind is always serious in a patient over 60 years of age. Many of our readers will be aware also that such infections are rather different to day from those observed ten years ago. It is very difficult to put any precise limit to the probable duration of the illness, its tendency is toebb and flow and part of the anxiety of those in attendance centres round the length of these phases. While specific treatment appears to have some effect in controlling the force and intensity of the infection, such measures cannot of themselves bring it to an end.

Our study of the bulletins (including the temperature records) up to the time of going to press leads us to infer that the force of the infection is gradually spending itself and with maintenance of the patient's strength we may look for a favourable issue though early and dramatic signs of improvement are unlikely. Meanwhile the affectionate thoughts of ever, member of the Association will be with the King our Patron and the Queen and as doctors we shall wish to give a message of confidence to the colleagues who bear the heavy strain involved in attendance at the Royal bedside.

PROBLEMS OF THE SLUM

It may be remembered that at the autumn dinner of the British Medical Association last year, Mr Chamberlain, speaking as Minister of Health, stated that the supply of new houses was becoming so nearly adequate, that he proposed in the immediate future to take action in regard to the very urgent matter of dealing with slum areas. He appealed to the medical profession, along with others, to help in this by expert knowledge and advice, and by assisting to create a proper and encouraging public opinion. It would scarcely be possible to have a better aid in this direction than the volume entitled *The Slum Problem*,¹ by Mr B. S. Townroe. It has a short commendatory introduction by Sir J. Walker Smith, formerly Director of Housing at the Ministry of Health, and Mr Townroe has himself had experience in that department of the Ministry, and has also for several years been chairman of the Housing Committee of the Hampstead Borough Council, and acted as consultant to the Building Research Board. Such an experience may be taken almost as a guarantee that the book contains facts on which reliance may be placed, and suggestions which are well balanced and practical. The problems of the present situation with regard to slum areas are extraordinarily difficult, their exposition correspondingly demands qualities which are not universal possessions. They lend themselves to easy generalizations and facile statements which may pass on the political platform, or even in Parliament, as evidence of good intentions, but do not contribute in any way to creative or constructive action. Mr Townroe's book is intended to supply speakers and writers on its subject, members of local authorities and housing committees and associations, and others with information which can be turned to practical use. It may be strongly recommended also to medical men and women who are interested in health administration and propaganda, but who sometimes do not know as much of housing matters as of some others, and to elementary school teachers, who are not always sufficiently aware of the home conditions of some of the children in their charge, though these conditions, as was demonstrated by a report of the Medical Research Council,² influence the intelligence of the children to an extent of the order of one third. It is an important consideration that progressive improvement in home conditions should react favourably, not only on health, but on intelligence. The complacency with which certain large industrial, or even residential, towns proclaim themselves as being "without a slum" is a little disquieting. It depends, of course, on the definition. It is possible for a lord mayor or mayor so to define a slum as to be able truthfully to say that there is none in his city or borough. Mr Townroe quotes a definition, but it is not an exact one, and he deals broadly with his subject so as to include rural as well as urban conditions, whether they are due to the ancient timbered house, to back to back erections, to the cul-de-sac, to jerry-building, to the rows of depressing hovels in many mining villages, or to any other cause. Some localities are obviously much better than others, and the authorities of such places, whether then advantaged by due to good fortune, or wisdom, or both, are to be congratulated. In some of the worst towns the local authority has made almost heroic efforts to cope with the worst spots therein, and they are heartily to be commended. So are many voluntary associations and individual landlords of property which, without assiduous and personal attention, would inevitably have so deteriorated as to have become unfit for human habitation. Yet the conditions over large areas remain appalling. As a metropolitan sample may be taken

¹ *The Slum Problem*. By B. S. Townroe. M.A. Hon. A.R.B.A. With an introduction by Sir J. Walker Smith, M.Inst.C.E., F.S.I. London 1928. (Cr. 8vo pp. 229, 6s. net.)
Special Report Series No. 74. The Relation of the Intelligence of School Children.
1923. 1s. net.

the "Report on and Survey of Housing Conditions in the Borough of Shorehitch," recently published by the Wear-dak Press. The Hoxton conditions are no doubt very distressing because "the problem of housing is inextricably interwoven with that of sheer poverty, often of landlordism and tenant alike," but they are not unique or even peculiar. Such reports as this are valuable as arousing opinion to the need for immediate and drastic action, but there is often a tendency to assume that the one cause is bad landlordism, and the one remedy a supply of money. Great merits of Mr. Townroe's book lie that he does not allow us to forget that slums may be made by errors of conduct as well as by errors of structure, that under the former heading it is the tenant at least as often as the landlord who is at fault, that under the latter heading planning and lay-out may be as important as actual building, actual experience having proved that 85 per cent, or even more, of the cost of reconstructing a slum area may be recovered by its suitable re-planning. Mr. Townroe deals practically with the difficult question of compensation, and with such remedies as reconditioning, high tenements, garden towns (as distinguished from suburbs), of which Ietchworth and Welwyn Garden City are pioneer examples, and educated woman management of property let at weekly rentals, and he attaches due importance to education, whether of the child or adult, so that the "slum mind" as well as the slum may be eliminated.

MEDICAL AND NURSING SERVICES IN THE AUSTRALIAN BUSH

It requires a considerable effort of the imagination for the stay-at-home native of these islands to appreciate the difficulties facing the medical profession in the vast and thinly populated area of Australia. An Australian visitor once described Great Britain as having a "finished" appearance—meaning that communications and other services necessary for a comfortable existence were highly developed, that nature generally had been brought under control and that communal provision had largely removed the need for dependence on individual effort—while his own country was "in the raw." It is true, of course, that the cities and closely settled areas in Australia are as highly organized as any part of this country, but even after the exclusion of the innerless areas, which are almost totally uninhabited, the greater part of the Commonwealth has a population of less than one person per square mile, and is still awaiting development. A main problem is, therefore, the provision of medical and nursing services in the "back blocks" which are but sparsely peopled and in which travel is slow and difficult. On January 14th (p. 67) we published a reference to the work of the Victoria Bush Nursing Association, which exists to promote the establishment of a district nursing service in the country districts of that State, and which has rendered most valuable service since its inception in 1910. The report of the Association for the year ended June 30th shows that there were then in existence 59 centres including 14 with cottage hospitals, at the end of the previous year in June, 1927, the number of centres was 55 including 9 hospitals, so that definite progress has been made towards the ideal of having a hospital at every centre. It may be mentioned that at one point until the opening of a centre this year, there was no doctor or trained nurse within fourteen miles. The members of the association's nursing staff are all trained midwives, and undertake a considerable amount of maternity work, with highly satisfactory results, in addition to providing ante-natal and post-natal care. They also fulfil the duties of school nurses in most districts, examining the children and reporting defects, and giving instruction in hygiene and kindred subjects. To illustrate the nature of

the conditions it may be added that in many cases eight or ten schools are required to serve the district within the area of a centre, and that these schools have often only ten or fifteen pupils, in one case the nurse visited five schools in her district, the aggregate number of pupils being eighty. The country division of the Victorian Civil Ambulance service aims at the provision of approximately thirty stations, covering the whole of the State, and during the year 1927-28 new cars were presented to four districts, provision for maintenance and replacement being undertaken by local committees. Twenty-one stations are now in operation, and, as a further illustration of the conditions encountered, it is significant to note that in one instance the average distance covered by the ambulance for each case was almost ninety miles, in several other instances the average exceeded sixty miles, and for the whole service it was over seventeen miles per case. In connexion with these points it should be noted that they apply to Victoria, which is by far the smallest and the most densely populated mainland State in the Commonwealth. Conditions in other parts of Australia are therefore even more difficult. A map published by the Australian Inland Mission illustrates admirably the situation in respect of medical relief, showing that in some areas medical aid posts—where doctors, bush nurses, hospitals, or nursing homes are situated—are separated by distances ranging from 100 to 250 miles. The indication of "suitable bases for flying doctors" suggests an interesting possible development. There have already been cases in which the aeroplane has been utilized for the transport of practitioners, patients, and medical stores, and it may well be that in the future the light machine will normally serve the Australian country doctor for his hundred-mile professional calls, while wireless may be employed to summon a large aeroplane for ambulance work when required.

RADIUM, CANCER, AND THE PUBLIC

It is perhaps too much to hope that the views on the present place of radium in the treatment of cancer, expressed by Mr. Malcolm Donaldson in a letter we publish this week at page 1008, will put a stop to the pernicious misstatements now appearing in most of the articles on the subject in the popular press. There is at the moment a serious shortage of radium, and this shortage may in large measure be attributed to the fact that the chief source of the world's supply is virtually a monopoly. Those qualified to use radium in the treatment of disease are being hampered in their work by lack of adequate supplies, and many cancers now treated by surgery alone would in all probability be treated by means of radium if sufficient supplies of this agent became generally available. It is right that the public should know these facts. But the temptation to make a good case appear even better by backing it with a white lie or two seems to have been too strong for some of the writers now active in administering health instruction to the general public. These undisciplined propagandists are not content to say simply that radium may now take the place of "excisional surgery" in the treatment of cancer in certain sites; they must pretend not only that all cancers, at whatever stage of their development and wherever situated, will now yield to radium, but that this would be freely admitted by the medical profession were it not for the implacable determination of the surgeons to maintain their ghastly monopoly in cancer. Alas, says one writer, "wherever radium is to be had the surgeons ought to be prevented from cutting out any more tongues or noses or amputating any more breasts." This is mischievous claptrap. By all means let newspaper readers know the established facts about the use of radium in the treatment of malignant growths, but a clearing away of the fog of misrepresenta-

tion that has been allowed to envelop the whole subject would appear to be the first necessity. Mr. Donaldson raises two other issues in his letter—namely, the need for diagnostic centres at which cases of cancer might be recognized in their earliest stages, and the importance of teaching the public more about malignant growths. Both issues merit close consideration by those concerned with the public health. Whether, however, it is better to educate the public specifically in the symptoms of cancer, thus running the risk of inducing in many persons a morbid self-regarding vigilance, or to concentrate on the value of periodic medical examination, opens up problems too large for discussion in a brief annotation. But the education of the public is a matter on which the medical profession will soon have to make up its mind, in principle and in detail, for if the public is not given instruction by those qualified for the task it will seek other mentors, with perhaps disastrous results.

MIRROR WRITING

MIRROR WRITING is that variety of script which runs in an opposite direction to the normal, the individual letters being also reversed. The writing is therefore illegible until held up before a looking-glass—a familiar example of mirror-writing is seen in the imprints upon a blotting pad. Mirror-writing is met with in most diverse circumstances, and in all classes of persons, from the mentally deficient to the genius. Adults and children may show it, and it may be done consciously and unconsciously. Yet it is sufficiently infrequent in its occurrence to render it a subject of interest when observed. Dr. Macdonald Critchley has written a most interesting little book entitled *Mirror-Writing*,¹ in which he tells all that is known about it. The book contains specimens of such writing done by infants in schools, where perhaps it is most often seen, and a page from a notebook of Leonardo da Vinci, of whom it has been said that he adopted this form of script to hide his observations from the inquisitions of the Papal authorities, though the suggestion seems to imply that his genius was less shrewd than his other work would make it appear. There are also specimens of spontaneous bimanual mirror-writing done by a normal individual conscious of his doings, and a beautifully written letter by an old lady, the subject of right-sided hemiplegia, who thought that she was writing just as she had always done and as everyone else did. An oddity such as this mirror-writing, so widespread and so different in its conditions of production, suggests that the finding of a common cause for such varied exhibitions may be difficult, and so it appears from Dr. Critchley's book. It is reasonable to explain that the paraplegic whose right side is powerless writes mirror-fashion with his left hand because there is probably a derangement of the visual component of speech present, and the patient is therefore subject to the independent activity of stored-up memories localized in the right hemisphere. Writing in such cases may be impossible to initiate at will, but when it arises in response to more primitive impulses it will be executed in its most automatic fashions, mirror-wise. But such an explanation would not seem to apply to the mirror-writing of children. Yet it is not as irrelevant as may appear. Reversals are common in infant attempts at writing. The child is taught to write in a certain fashion, there is no reason behind it, but only rule, and a rule that custom has not fixed in his mind. So that on occasions he breaks a rule that is of little weight to him. It has been said that mirror-writing is a sign of left-handedness, and observations lead the author to the conclusion that it is more common among the left-handed.

¹ *Mirror Writing*. By Macdonald Critchley, M.D. M.R.C.P. *Psychic Miniatures Medical Series* No. 11. London: Hegan Paul Trench Trubner and Co. Ltd. 1928. (Pott 8vo pp. 80. 6 figures. 2s. 6d. net.)

WILLIAM BRINTON, M.D.

We wonder how many of our readers, apart from those who have specialized in gastro-enterology, would know what was meant by "Brinton's disease." There are perhaps few better examples of the proverbial prophet than that of Dr. William Brinton, who was the first to describe the rare condition which he named *hinitis plastica*, and was one of the founders of modern systematic gastro-enterology. In a sympathetic address delivered at the last general meeting of the American Medical Association in the Section on Gastro-enterology and Proctology, Dr. Joseph Sailer of Philadelphia gave an interesting account of the life and work of this physician, who died in 1867 at the comparatively early age of 44. He was house-physician, demonstrator of anatomy, and medical tutor at King's College, lecturer on forensic medicine and afterwards on physiology at St. Thomas's Hospital, and physician to the Royal Free Hospital. He was an excellent teacher, his clinics at the Royal Free Hospital were crowded, and he conducted a very large practice. In addition to about forty articles in medical journals, many on *anatomical topics*, he wrote four books, which dealt respectively with gastric ulcer, diseases of the stomach (which contains the description of *hinitis plastica*), diet, and intestinal obstruction. Of these Dr. Sailer regards the last as the most valuable, and that on diet as the poorest. In the work on intestinal obstruction Brinton advocates early operation, suggests the possibility of entero-enterostomy, which he appears to have tried on animals, objects to purgatives, and pins his faith on three drugs—namely, opium, tobacco (by enema), and belladonna. Apart from his contributions to medicine, Brinton was a keen Alpine climber, an excellent draughtsman, and a brilliant conversationalist. A portrait of him is to be found in the Royal College of Physicians.

MEDICAL MEMBERS OF LOCAL PUBLIC BODIES

We hope to publish shortly a list of medical men and women now serving on local public bodies, and we invite the help of our readers in obtaining the necessary information. Medical members of the following bodies are asked to send brief particulars to this office on a postcard addressed to the Editor: County Councils, County Borough Councils, non-County Borough Councils, Urban District Councils, Rural District Councils, also medical co-opted members of Education Committees, Maternity and Child Welfare Committees, Mental Deficiency Committees, and medical members of Boards of Guardians. Information is desired also about members of the corresponding bodies in Scotland—County Councils, Town Councils, Parish Councils, and Education Authorities, etc. Medical officers of health may be able to assist by furnishing notes of medical members of the local authorities with which they are associated. In response to the requests already published details have been received regarding medical members of more than sixty local bodies. Such information is always useful, and it will be especially valuable during the coming year in view of approaching legislation.

SIR LEONARD ROGERS, C.I.E., M.D., F.R.S., has been appointed Medical Adviser and President of the Medical Board, India Office, in succession to the late Major-General J. B. Smith.

We regret to announce the death of Dr. James Wilkie Smith of Ryton-on-Tyne, one of the oldest and most widely respected medical practitioners in the North of England. A memoir will appear next week.

THE ORGANIZATION OF MEDICAL RESEARCH IN INDIA

Recent events have brought into no little prominence the subject of medical research in India and its organization by Government, both in relation to the needs of India as a whole and with due regard to scientific research work in other parts of the Empire, including Great Britain. Our consideration of the matter may appropriately be prefaced by a brief historical note.

HISTORICAL

Organized medical research in India dates from the appointment, nearly sixty years ago, of Dr Timothy Lewis and Dr D D Cunningham as whole-time research workers in India. The first Indian Medical Congress in Calcutta at Christmas, 1894, which Mr Ernest Hart attended when Editor of the *British Medical Journal*, sent resolutions to the Government of India advocating more medical research, and the outbreak of plague in Bombay in 1896 led to the establishment of the plague laboratory there under Haffkine. In 1899 Surgeon General Harvey recommended the formation of a bacteriological department, in 1905 thirteen officers were sanctioned for research work under the Government of India, and the Central Research Institute was opened at Kasauli in the following year.

In the year 1911 a great step forward was made when, on the advice of the late Sir Pardey Lukis, the Research Fund Association was formed under the Government of India with an annual income of five lakhs of rupees (£35,000) to administer the Medical Research Department (as the bacteriological department is now called), with the *Indian Journal of Medical Research* as its organ.

In 1920 the late Professor E H Starling visited India at the invitation of Government, and reported on a scheme to build a new central research laboratory; he recommended Delhi as its site, but financial stringency held up the project. Last winter a committee was formed under the chairmanship of Sir Walter Fletcher, F R S, secretary of the Medical Research Council, and with Colonel S R Christophers, F R S, as its secretary, to report on the reorganization of medical research in India, including the proposals of Professor Starling. The other members of the Committee were Lieut-Colonel S P James, medical officer and adviser on tropical diseases, Ministry of Health, and Dr R Row, professor of pathology, Grant Medical College, Bombay. After visiting all the important research centres this Committee has recommended extensive modifications of the Starling scheme in accordance with the altered conditions of to-day. That scheme included provision for clinical and pharmacological work, this has since been provided for in the Calcutta School of Tropical Medicine and in proposed pathological institutes in connexion with the Bombay and Madras Medical College Hospitals. These changes have also done away with the necessity for locating the new Central Research Institute in a large city such as Delhi, with a great expenditure on buildings.

PROPOSALS OF THE FLETCHER COMMITTEE

After studying the matter in all its bearings the Fletcher Committee has found a very appropriate site at Dehra Dun for the Central Medical Research Institute. This site is in close proximity to other scientific institutes, with ample land and some fairly suitable buildings, and also a very good climate for a station in the plains. Dehra Dun, though not one of the large cities of India, is a place of some importance, with direct access by rail to Delhi. It is in the Meerut division of the United Provinces.

The Committee's scheme for a headquarters for an All India medical research organization includes pro-

vision for six sections. These, briefly enumerated, are as follows: (1) Epidemiology and Statistics, (2) Bacteriology, together with a serum and vaccine section in the present Ka mili Laboratory, and Immunology to include work at cholera and plague, (3) Biochemistry and Pharmacology, for which there is no provision at Kasauli, (4) Medical Biology to include medical entomology, protozoology, and helminthology, (5) the Malarial Survey of India, already in existence under Colonel Christophers, and (6) Nutrition, now being carried on by Colonel McCarrison.

The Committee advises further development of provincial research institutes in the principal cities, with six additional superior research posts. In its opinion provincial institutes should continue to work as at present on their own lines, developing their particular spheres of usefulness, each under its own provincial Government. But direct and indirect assistance should be given to the work of these institutes, along lines indicated in the report.

In regard to administration, the Committee does not recommend any radical change. The successful Research Fund Association should, it holds, continue to administer the Research Department, but the new Central Research Institute should have its own governing body. The Committee believes that the problem set before it can be solved by building upon the foundation of past experience and by securing continuity for the evolutionary process which has been going steadily forward since 1900.

In regard to the recruitment of research workers, the Committee advises that some of these should continue to be obtained from officers of the I M S, both British and Indian, but it suggests that an increasing number of research workers will have to be recruited from outside India. To allow the right stamp of men to be obtained it advises the formation of a Recruitment and Appointments Board of senior administrative and research medical men, and that this board should have the help of a consultative committee in Great Britain of four members nominated respectively by the India Office, the Ministry of Health, the Medical Research Council, and the Royal Society, who should also belong to the governing body of the Research Fund Association. This board should also make the appointments to the provincial research laboratories.

Not the least important and suggestive passages in the report are to be found near the beginning, where the terms of reference and then interpretation are discussed. The Committee insists that "medical research" must be read in its widest and fullest meaning, and that no sound system of medical research can be established unless living organic connexion is set up and maintained between applied work on the one hand and work not of immediate utilitarian character on the other. The Committee wisely places emphasis also on the importance of interpreting "medical research" to include much more than the study of actual disease. This phrase it takes to include all processes of advancing knowledge, whereby the human body may be brought to the fullest development of health and efficiency of which it is capable under good conditions of environment, and protected from disease and other injuries, or aided in its repair. Viewing the terms of reference in this broad manner it became apparent that the questions put to Professor Starling in 1920 now formed only one of a set of connected problems of the greatest importance to India, and reaching, indeed, far beyond that country.

What appears to us to be the keystone of the Fletcher Committee's report is its recommendation not only for enlargement of the medical research service in India, but for acknowledgment of the essential value of research work as such, and as a corollary the assignment to its personnel (given due capacity and experience) of equal status recognition and pay with those in charge of administrative work. The problem of recruiting good men for the medical services of India would become far easier if it were known in the medical schools that India is once more prepared to offer really scientific careers in medicine with adequate remuneration and status.

NUTRITIONAL RESEARCH IN INDIA

In a special section of its report the Committee deals with the future of "Nutritional research in India"—a problem it had been specifically directed to investigate.

No part of the report is of greater interest than this, and in none is the path of progress for medical science more clearly indicated. The Committee recognises that adequate provision for research on nutrition is essential, not only to the successful study of specific problems of disease in man and his domestic animals, but to the promotion of physical efficiency in both. Insistent as are the obvious problems of acute and epidemic diseases (such as plague, malaria, influenza and kala-azar) to meet which research in India has been sporadically organized in the past, these are not more urgent in reality than the less dramatic medical problems of daily life. "In the light of modern discoveries we know, for instance, not only that recognizable and named diseases may come to vast numbers of a population from diet which is faulty in quality, even if adequate in quantity, but also that less defined but no less tragic evils may come in the form of diminished health and energy and lowered resistance to infection." In no country in the world is the truth of this statement more apparent than in India where the work of McCay in 1910, and of McCarrison in later years, has demonstrated the connexion which exists between faulty nutrition and the physical inefficiency and low powers of resistance to infection exhibited by millions of the Indian people.

This section of the report deals at some length with the groups of phenomena to be studied in nutritional science, as well from the quantitative and qualitative as from the economic points of view. Emphasis is laid on the necessity for re-examining the older and basic knowledge of nutrition, derived from studies in temperate climates, in the light of climatic conditions in India, for while this knowledge may stand the test of re-examination it is possible that it may require some modification. Many current views of pathology and bacteriology require reconsideration in the light of the newer knowledge of nutrition. In these activities "it is not likely that any country in the world has more to gain than India herself, or more to give to other countries as the work progresses, in new knowledge of the greatest scientific and practical value."

In harmony with the recommendations of the Royal Commission on Agriculture, the Fletcher Committee recognizes the intimate community of interest between workers on nutritional science, whether in fields of "human," of "animal," or of "plant" nutrition, and it indicates the great and mutual value of close association between medical and agricultural interests in studies of human and animal physiology and pathology.

Having thus drawn attention to the importance of nutritional research to the Indian peoples and dealt with the inadequacy of the present provision for its prosecution, the Committee proceeds to make recommendations for the great increase and extension both of the existing unit for nutritional research, under Colonel McCarrison at Coonoor, and for the establishment throughout India of new units in every important centre of medical research and higher teaching. Particularly does the report deal with the part in the scheme offered for a new Central Institute for Medical Research, which should be taken by nutritional studies. With the detail of these recommendations we do not propose to deal, since no doubt they will receive careful consideration by the authorities concerned. We hope, however, that it may be found possible to carry them into effect and to combine them with the independent recommendations of the Royal Commission on Agriculture, which provide not only for an Institute for Human Nutrition in India, but for an Institute for Animal Nutrition, both establishments working in close touch with each other.

In perusing this section of the report we are impressed by the masterly way in which the case for nutrition is presented, by the great importance attached to nutritional research as a result of the Committee's labours in India, by the vast opportunities which India presents for such research, and by the scope which it affords for young men of science imbued with the pioneer spirit of investigation. If the recommendations of the Fletcher Committee in regard to nutrition be adopted in combination with those of the Royal Commission on Agriculture then India will be equipped for nutritional research, and the ultimate benefit

to India, to the Empire, and to mankind will be great in proportion to the culture and capacity of the men chosen to organize, systematize, initiate, and carry on the work.

THE ROCKEFELLER OFFER AND THE COMMITTEE'S PROPOSALS

Shortly after the comprehensive inquiry of the Fletcher Committee an announcement was made in India that the Rockefeller Foundation had offered to the Government of India about £100,000 to build and equip a Public Health Institute in Calcutta, opposite the School of Tropical Medicine, to be staffed and administered by the Government of India. On September 6th last the Simla correspondent of the Calcutta paper, the *Statesman*, reported that the Government of India had considered this offer in relation to the Fletcher Committee's recommendations, and had decided to adopt the suggestion of the latter to adapt an available site with buildings at Dohra Dun as the new Central Research Institute, at a cost of six lakhs of rupees and to provide three lakhs yearly for the upkeep of the Calcutta Public Health Institute to be built by the Rockefeller Foundation (whose offer would be open until the autumn) at a cost of 15.61 lakhs.

As the two sets of proposals (which appear to fit very well into each other) have already been sanctioned by the Standing Finance Committee of Legislative Assembly in Simla there is every probability that these important advances will be carried through without much further delay, and that by such means medical research in India will be placed on a firm footing to the lasting benefit of the country.

Noa et Vetera.

A SEVENTEENTH CENTURY CURE FOR SCIATICA

THE prescription set out below was recently found in the archives of Rochester Cathedral by my friend Miss I. J. Churchill, F.R.Hist.Soc. It was written on a blank space in the *Register Spirituum*. I should think that some poor clerk or official suffering from the complaint had had it given to him by another, and had made a note of it at the time on the only available bit of paper. It is so quaint and so characteristic of the period, seventeenth century, that I thought it would be worthy of a space in the "Noa et Vetera" column. It runs as follows:

A VERIE GOOD MEDICINE FOR THE SCIATICA

Take an ounce of fine Venice Treacle of the best & penne worthe of neates fote oyle, an ox gall and two penneworthe of aqua vite, mingle all this together and make of as it were a salve and sprede the same upon a peece of white Leather one (on) the flesshie side and Laie the same to your place of Greefe, but before you do the same take parte of the same mixture and annoynte your place of greafe with it against a good fier and lett it soke in and when it is well annoynted before the saide fier Laie it unto the place of Greefe as afforesaide the Space of xxiiij houres. Then take it off (f) and Laie freshe unto the place, this is to be used the space of viij or x daies with freshe (ANNOYNTING) every xxiiij houres annoyntinge and chafinge yo place of greafe against the fier and with goddes helpe it will heale it.

The ingredients are simple and compound. Venice treacle as late as 1753 contained sixty-two different drugs. By 1785 it was called "a pompous and useless medication." Its active ingredient was opium. It is interesting to note the use of bilor; this was believed, and still is to facilitate the penetration of a drug through the skin. I am afraid the aqua vitae, or strong alcohol would somewhat thicken the gall, though it would prevent putrefaction. The white leather is still often made use of when applying a permanent plaster. When I was young Scott's dressing was generally applied on kid skin. Note "Chafinge" = modern massage.

MANCHESTER AND SALFORD

BY

L. V. BROCKBANK M.D. F.R.C.P.

THE Meeting of the British Medical Association is to be held in Manchester and Salford next July. The relations of the two cities are strange. They are so near together and yet so far apart. They are near because they are only separated by the River Irwell, a stream which at this part of its course rivals the Meander in finding the longest

distance between two points. It is about fifty yards wide here, and Manchester is on its left hand bank—a compass point is of no use—Salford on its right bank. But they are even nearer than this, for two important residential suburbs of Salford—Higher Broughton and Kersal—are on the Manchester bank and entirely continuous with the adjoining part of Manchester, their boundaries in daytime being marked only by policemen on point duty in different coloured helmets and it might by different lighting systems. Whilst so near and even interlocked in a territorial sense, they are as far apart as possible for local government purposes, each having an entirely independent mayor and corporation of its own, Manchester's head being a lord mayor. Originally Manchester was within the authority of Salford, which was a royal demesne with a royal manor the King holding lands in it, but although once so united

in a harmonious alliance they were granted a legal separation in the fourteenth century, and have never made it up again, in spite of various approaches for the purpose on the part of Manchester. By this deed Manchester became a common manor, Salford remaining a royal demesne, and still being a royal manor, which it proudly, and justly, mentions as occasion

arises.

After the separation over ensuing centuries Manchester forged ahead, and its population is now about 750,000, and that of Salford 250,000, but many of the latter number are Manchester people who live in the Broughton and Kersal suburbs of Salford.

Manchester's civic life centres in its Town Hall which is a very large building in Gothic style facing Albert Square, an open space of proportionately large area from which a proper view can be had of the

THE MANCHESTER ROYAL EXCHANGE

tall spire and its handsome clock with dial, figures, and hands that can be seen from miles away. The business centre of both towns is the Manchester Royal Exchange, the largest exchange in the world where at high 'change 5,000 or more members transact business, chiefly in cotton, but in all trades except coal and produce each of which has an exchange of its own. Millions of contracts are made yearly

in a harmonious alliance they were granted a legal separation in the fourteenth century, and have never made it up again, in spite of various approaches for the purpose on the part of Manchester. By this deed Manchester became a common manor, Salford remaining a royal demesne, and still being a royal manor, which it proudly, and justly, mentions as occasion arises.

on the Royal Exchange by word of mouth, and confirmed afterwards by contract notes, and but few are not kept. Business has been sadly to seek with us lately, and many times may the following conversation have been heard on the "boards" between business friends: "Morning", "Morning", "Owt?" "Nowt", "Morning", "Morning".

Manchester is not uncommonly called "Cottonopolis," a term which, if ungainly, is not unjust, because it is the centre of the cotton industry of Great Britain, which, it is estimated, directly and indirectly gives employment to 10,000,000 of the population, and in the mills of which £210,000,000 are invested. Some of the finest cotton thread of the world is spun in the heart of Manchester, and has been since Robert Owen, the socialist reformer, began to spin fine yarns in 1790, and I have seen yarn so fine that 140 miles length of it weighs only one pound. It would require an *Enobarbus* to describe the infinite variety and fascination of some of our *Cepea calico* printers' work on gauzy muslins made from Egyptian cotton. It is hoped that visitors competent to judge will have an opportunity of checking the truth of this statement next July.

Manchester has many industries besides that of cotton, and so has Salford, but space will only permit reference to the great channel—the Manchester Ship Canal—by which is brought, in ocean-going steamers up to 15,000 tons burthen, the raw material for the factories, and our beef, corn, eggs, bacon, and cheese. The Ship Canal offices are in the fine new ten-story-high building in Upper King Street, which the company built and owns. In this building, the tallest in the city, the Manchester Chamber of Commerce has its headquarters.

Salford has many factories, but few warehouses or commercial buildings. All the commerce of the two towns is transacted in Manchester, with its miles of streets lined by magnificent warehouses, in which goods are stored and packed, and from which they start on their journey by rail or Ship Canal to the uttermost ends of the earth. Manchester is Salford's shopping centre, entirely for the classes and almost entirely for the masses. The only Salford shop that I have ever heard of that has supplied the "quality" with necessary things was Hobson's, the boot shop—and that was Hobson's choice.

The approaches to Salford from Manchester are not cheering, it is a striking contrast to cross the river from one of Manchester's busiest and finest shopping streets into cheerless Chapel Street, Salford's main artery. This is a wide street, running to Bevel Square, in which is Salford's small, handsome town hall. The architectural features of the street begin at the Education Offices and the fine Salford Roman Catholic Cathedral. Further on, Salford Royal Hospital adds dignity to the appearance, and then the broad north road to Bolton, beginning with a fine crescentic sweep which overlooks a typical Irwell horse

shoe bend and some of Salford's factories, and leads to the handsome buildings of the Technical School, is a worthy highway for any town.

Salford at present provides the cattle market for the two towns and neighbourhood, and if any citizen, informed as to local affairs, should forget the day of the week, he can

always get a grip on Tuesday by seeing the raw material for food on its last appearance in its Anglo-Saxon forms of oxen, sheep, pigs, and calves on its way from Salford Market to the extensive Manchester abattoirs, where it is made suitable to appear on the menus of the two towns as beef, mutton, pork, and veal.

The relationship of the two towns, as I said before, is curious. Salford would be very badly off indeed without its big offspring, and the loaves of bread, not crumbs received from its bountiful table. The Manchester (not Salford) Ship Canal has nearly all its extensive dock in Salford because of the need to use the River Irwell for dock construction. The Manchester Corporation has £6,735,000 invested in the Canal, with members of its corporation forming a majority of the Board of Directors. Salford has no money invested in it, yet its rates benefit from the docks and warehouses to the extent of 7½d in the pound, whilst Manchester only receives 1½d farthings in the pound. Much the same

benefit from rates results from the position of the railways. Yet with all this help Salford rates are 25 per cent higher in the pound than Manchester's, and most of its valuable rateable ground is occupied. In further negotiations for amalgamation we may have an opportunity of seeing Manchester play the part of a modern commercial Sisyphus in its efforts to Salford.

Salford makes some amends to Manchester by providing space in a catpillar loop of the Irwell for the Manchester racecourse, and Manchester's premier amateur Rugby football club has moved into Salford territory for a suitable ground. Salford favours professional Rugby football, whilst Manchester provides two Association teams, and is about to provide another.

In the cricket world the Old Trafford ground is unsurpassed anywhere in England for players and 30,000 onlookers. It is taxed to its utmost when the old struggle of the Wars of the Roses is renewed on a fine sunny Bank Holiday, when as many thousands as perished in the

old wars and lie under the sod have to be accommodated on the turf within the playing ring for the three days' grim and dogged struggle. Both towns can compete favourably with each other, and with any other town, in the number of dog- and dirt-racing tracks, cinemas, and dance halls.

Manchester provides the two towns with their daily newspapers, including, of course, the *Manchester Guardian*, of world wide circulation, fame, and good repute. The

MANCHESTER TOWN HALL, ALBERT SQUARE

SALFORD TOWN HALL

local doctors and the press are on very friendly terms in spite of our general professional distaste for personal publicity, which our journalistic friends do not appreciate and would like to see less of. Not even the premier paper, however, understands the difference between the British Medical Association and the General Medical Council, and the editorial thwackings that are administered to chastise the profession as occasions arise are, accordingly, liable to fall on the wrong shoulders. We have only two theatres now instead of four, the Theatre Royal and the Comedy Theatre, which have in their time played many parts in our social life, having recently been turned into picture houses.

Manchester has had a reputation as a great musical centre since a German pianist, Charles Hallé, settled in the town and formed an orchestra in 1858, mainly of principals of his own nationality, and which was supported chiefly by the many German residents of the town. Concerts have been given each succeeding winter by the Hallé band, and under various conductors since Hallé's death. Britishers have been taught the beauties of music by it, so that now they form the great majority of the audiences at the concerts. Hallé conferred a further benefit on the town and neighbourhood by securing the foundation of the Manchester Royal College of Music in 1891. This has had a very successful career, and has trained local students so well that, to take one side only of success, instead of the Hallé Orchestra being recruited from abroad, not only all the principals, but nearly forty members of the band have been educated at the School of Music. Under the present conductorship of Sir Hamilton Harty the Hallé Orchestra, as it is still called in honour of its originator, is a magnificent instrument, envied by all musical centres, and it is a matter for regret that it cannot be got together in July, when most of its members will be leading or conducting in holiday resort orchestras. "Listeners in," however, will have had the pleasure of hearing the orchestra play on several occasions.

Primary education in Manchester and Salford is carried out on similar and efficient lines, with all the modern fine buildings and fresh air schools and school medical officer developments, but whilst in Salford the medical side of educational care is under the authority of the medical officer of health, in Manchester it is under the control of the Education Committee, which appoints a special medical officer to supervise it, and the Manchester medical officer of health has nothing to do with it.

The Manchester Grammar School, which was founded in 1515, and the Chetham Bluecoat School, founded in 1654, still carry on their good educational work. Secondary education is provided by both towns in the form of ordinary schools, domestic economy, art, and technical schools. Manchester's provision is naturally much more extensive than what Salford requires, and supplies the highest educational facilities in the Victoria University of Manchester, in which is a medical faculty, with hospital tuition provided in the Manchester Royal Infirmary, founded in 1752, which for the moment I will content myself with saying is second to none in the United Kingdom.

In religious matters Manchester has its Bishop and Cathedral of the Established Church, Salford its Bishop and Cathedral of the Roman Catholic faith. The Manchester Cathedral, with an ancient and honourable history as a collegiate church, has some impressive architectural features with very fine woodwork in its stalls. Salford Cathedral is a fine building, and so is the Church of the Holy Name in Manchester, with its handsome, newly completed tower which will be admired by many visitors in July, 1929, because of its being near the centre of the Association meetings.

The John Rylands Library is one of the treasures of the city. Its priceless contents include 3,000 manuscripts, many unique, and the famous St. Christopher print, the earliest known piece of printing in the Western world, with an undisputable date (1423) which is alone sufficient to make any library famous. The cabinet for such a collection of literary gems is a wonderful specimen of modern Gothic architecture. A fuller account of the library will be given in the *Book of Manchester*.

The British Medical Association Divisions of Manchester and Salford were formed in 1903, on a territorial basis, and contained an approximately equal number of members. They were the North, South, West, and Central Divisions, with the Central containing most of the consulting and specialist members. A need for co-operation soon became apparent, and in January, 1906, it was first proposed to form a standing committee of the four Manchester Divisions. This idea was developed further to include the Salford Division, and in June, 1907, the Joint Committee of the Manchester and Salford Divisions held its first meeting.

After the press of work involved in the inception of the National Health Insurance work was past, the feeling grew that still closer co-operation would be useful, and in 1915 the Manchester Divisions amalgamated to form the Manchester Division, the Salford Division deciding to continue its separate existence, as serving a definitely distinct area. At the present time there are 414 members of the Association and 305 non-members in Manchester, and 105 members and 81 non-members in Salford.

Passenger traffic congestion is a great problem in Manchester as in other big towns, but Salford is only troubled by it because its tramcars must come into the busiest street of Manchester, which is already overfull with its own vehicles. The Manchester tramways system is said to be the most efficient and finest in the world, and it can well be so. Its large cars carry seventy to eighty passengers in the "rush" hours, when every vehicle in the sheds is turned out. Large motor buses for local and distant service also enter the town in increasing numbers. The Manchester Committee has adopted a bright scarlet coat for its vehicles, and its trams and buses give a cheerful dash of colour to the streets.

Scotland.

Diet and Disease

A public lecture on diet and disease was given on November 21st by Dr. D. Murray Lyon, professor of therapeutics at Edinburgh, who said that modern research had shown that certain ordinary mixed diets which had long been considered satisfactory might, in fact, be otherwise. It had been found that animals fed on a diet consisting solely of cereals, pulses, and tubers failed to grow as fast or as large as they ought, and were apt to age prematurely. Control animals receiving the same diet with the addition of a little green food were found to grow more rapidly and thrive better. Similarly, in the human dietary celery or spinach added to the food appeared to supply something which was essential for proper development. In these experiments milk might replace the green knives with similar beneficial results, and it therefore appeared that the addition of green vegetables and milk to the diet of sickly, backward children would be beneficial. Rickets, which was a common scourge of city children in the past, was likely to be abolished altogether, now that the part played by vitamin D was more fully understood, and the adequate supply of this important ingredient might be ensured by adding to the diet fresh milk, butter, and eggs. The same group of substances also contained vitamin A, whose absence was apt to lead to increased susceptibility to infection. With regard to flour, the older methods of milling permitted all the necessary constituents of the grain to pass into the flour, but modern methods had robbed it of certain valuable elements. The resistant outer coat or bran of the grain, being indigestible, acted as roughage, and the wheat germ was rich in vitamins but both were removed in the modern process of milling. Constipation might often be avoided by the use of wholemeal bread. On the other hand, over-indulgence in food might lead to various passing alimentary troubles, while chronic overeating was of great importance in regard to the production of disease. With advancing years food requirements became less, although the appetite might remain as before. Increasing stoutness lessened the inclination for activity and tended to produce a continually deteriorating habit of body. Everyone deplored the poor state of the nation's teeth and many remedies had been suggested, but it was probable that better balanced diets during the

growing period and more careful attention to mouth hygiene would go far to abolish what was really a national disgrace. Owing to the variation of individual likes and dislikes it was impossible to lay down an ideal dietary, but it might be said that most people ought to reduce the amount of sugar and concentrated starchy food which they ate and exchange these for coarser forms of carbohydrates such as leafy vegetables and fruits, which yielded more vitamins and roughage, and at the same time more milk could advantageously be consumed even by adults.

Medical Service in the Field

A lecture was delivered by Mr G. H. Edington, M.D., F.R.C.P.S., on November 22nd, in Glasgow University, under the auspices of the West of Scotland Branch of the Historical Association of Scotland, on "Medical service in the field." The lecturer said that during the war the British army numbered 3,500,000 with R.A.M.C. personnel of all ranks amounting to 144,514, and that this corps had had to deal with sick and wounded arriving in the United Kingdom numbering well over two and a half million. At one time on the Western Front the regular R.A.M.C. officers were less than 10 per cent of the total doctors employed, most of whom were medical practitioners temporarily engaged by the army. In describing the differences in sickness rate which existed between this and previous campaigns, Mr Edington remarked that the contrast was nowhere more marked than in the case of typhoid fever. That cases of this disease had been remarkably few was in his opinion, attributable to the value of protective inoculation and to the patient research work that had been carried on in laboratories during many years before the war. The wiping out of typhus, which had occurred in a severe epidemic in Serbia, was also due to the application of principles founded on laboratory work. The lecturer also dealt with the organization of medical services in the field and described the chain of medical units from the regimental aid post down to the line hospital, and illustrated this with lantern slides and photographs which he had taken in Gallipoli, Egypt, and Palestine.

Veterinary Training in Edinburgh

An address on "The life and work of William Dick," founder of the Royal (Dick) Veterinary College, Edinburgh, was delivered in that college on November 20th, by Mr Alexander Miles, president of the Royal College of Surgeons, Edinburgh. Dr T. G. Nasmyth presided. The lecturer said that the meeting was being held for the inauguration of a founder's day and lecture at the Veterinary College because this was the centenary of the institution of professional examinations in veterinary art. William Dick had been in many ways a great man. He was born in the White Horse Close off the Canongate of Edinburgh, and was the son of a blacksmith from whom he early learned an interest in animals. Through his own efforts he had acquired a general education above the average for his time. Unaided and often in the face of opposition he had striven to raise the craft of farriery in Scotland to the rank of a recognized profession, and the Royal (Dick) Veterinary College was the visible result of his life's work. Having improved his own education he had felt impelled to pass on his knowledge of veterinary science to others, and he began to deliver lectures developing a comprehensive course of instruction in veterinary medicine and surgery. In 1823 on the suggestion of the University of Edinburgh the Highland Society undertook to stand sponsor for a public lecturer on veterinary surgery, and Dick was appointed to this post. The lectures were delivered in his father's forge in Clyde Street, and buildings on this site remained the headquarters of the college till 1916. As time went on there were added to the forge a stable, an animal hospital, a dissecting room, and a lecture room, of which the cost was almost wholly borne by Dick himself. Before he died in 1866, at the age of 73, he had accomplished the aim of his life, and had established in Scotland a school of veterinary science which now had few equals. Dick had not only possessed exceptional skill in veterinary surgery, but as a teacher he had been clear and lucid, and his qualities might well serve as a model for those who were preparing to follow his profession at the present time.

Indian Appointment for Edinburgh Graduate

Dr William Happer has been appointed director of venereal diseases to the Provincial Government of Madras, India, at a salary of £1,500 per annum. This appointment is the result of recommendations made by delegates of the British Social Hygiene Council who visited India during 1926-27, and is the first of the kind to be made. The duties will include the organization of treatment centres in Madras General Hospital, Madras Maternity Hospital, and various child welfare centres managed by the Red Cross Society and the Corporation of Madras, and those of lecturer on venereal diseases at the Medical School at Madras. Dr Happer, who is a native of Falkirk, after graduating in medicine at Edinburgh University, held the post of resident surgeon, and afterwards clinical assistant, in the Royal Infirmary, Edinburgh, under the venereal disease scheme of the Edinburgh Corporation. On the occasion of his departure Dr Happer was presented with a writing bureau from his colleagues in the Royal Infirmary V.D. Department, the gift being handed over by Dr David Lees, chief clinical medical officer under the corporation V.D. scheme.

England and Wales.

Medical Men and Public Affairs

An appeal to medical men to take a more active part in civic and medical politics was made by Dr I. G. Modlin, Mayor of Sunderland, at the annual dinner of the Sunderland Division of the British Medical Association held at the Palatine Hotel on November 22nd. Dr Roderick Macleod presided, and the principal guest was Professor Hugh MacLean. Mr Stanley Ritson, proposing the toast of "The Mayor and Corporation," said that it was the first occasion they had had as their guest a mayor who was also a medical practitioner, and they could not but feel pride in his many achievements. He had managed to combine a busy civic career with a busy practice, and had found time to fulfil the duties of an honorary surgeon at the Monkwearmouth and Southwick Hospital, where for many years he had carried on a large amount of surgical work with great efficiency. Dr Modlin, in his reply, referred to the changed conditions in the medical profession with the disappearance of the old family doctor. Doctors were now simply cogs in the wheels of social progress. Did they, he asked, take sufficient interest in politics, whether Parliamentary or civic, or the politics of the British Medical Association? The most dangerous foe they had to fight was the apathy of their members. After remarking that there was room for more members of the profession on the council, Dr Modlin said that in medical politics there had recently been issued an interim report of the Private Practice Committee on encroachments by local authorities upon the sphere of private practice. General practitioners had already lost a large slice of their midwifery, they did not seem to take much interest in ante-natal work, tuberculosis and venereal disease were slipping from their grasp, infectious diseases they had almost lost, and the hospitals were making greater and greater inroads on their means of livelihood. Did it not behoove the younger men to take a more active part in medical politics? It was not the older men who were going to suffer in the future, it was the interests of the younger generation of medical men that were at stake. The nation had entrusted to the corporations the care of the public health, and the nation demanded not only a lower death rate but a lower sickness rate. Public health work must progress, and unless the younger men grasped the present opportunity and took a share in co-operation with the authorities the independence and freedom of action of the medical profession would be lost, and they would become the victims of a bureaucratic service.

University of London Medical Graduates Society

The first extra-metropolitan dinner of this society was held at Birmingham on November 23rd, when some forty graduates were present, with the president, Sir St. Clair Thomson, in the chair. Sir Chilton Briscoe, Dr Dorothy Hare, Mr McAdam Eccles, and three other members came

from London, and Professor Hey Groves from Bristol, whilst Birmingham was represented by the two professors of medicine, Dr Wynne and Dr Ball, the professor of surgery, Mr Wm Billington, the professor of midwifery, Mr Beckwith Whitehouse, together with Mr Seymour Larling, Dr Graves, Dr Elizabeth Moffett, Dr Cloake, Dr Sykes, Dr Forsyth, Dr Lucy Masterman, and others. The president, in proposing "The Health of the King," said he was sure the toast would be drunk with great sincerity. Mr Billington expressed the pleasure of graduates in Birmingham at welcoming members from London and Bristol, and he hoped that future dinners would be the meeting places of members from many districts. He regretted that the Presidents of the Royal College of Physicians and the Royal College of Surgeons, both of them members of the society, had been unable to attend. Sir StClair Thomson, in an entertaining speech, traced the history and attributes of the University of London and its graduates, and of the society and its members, and complimented Birmingham in having, at least twenty five members. He was sure that the objects of the society, especially that of bringing medical graduates of the university into closer touch, was worthy of a greatly increased membership. Dr Dorothy Hare, one of the honorary secretaries, drew attention to the fact that the university now had about 4,500 medical graduates, and that the life subscription of the society was only £1. Mr McAdam Leeks alluded to the fact that these social gatherings were certain to foster a firmer university spirit, and that the society really had a function to perform which should have been exercised earlier. Mr Herbert Tilley suggested that after a Friday night's dinner it would be well that an extra metropolitan evening should be followed by golf, or even fishing, the next day, and hinted that he might present a cup for the former. After drinking the health of the president with acclamation the company adjourned for conversation and the renewing of old friendships. The next dinner will probably be held in Leeds, and the London dinner is fixed for the Tuesday night before Presentation Day.

Cumberland Infirmary, Carlisle

The committee of management of Cumberland Infirmary, Carlisle, has decided to establish a pathological department in order to deal with the needs of the institution and also of a wide surrounding area in this respect. A subcommittee was set up at the end of June to investigate and report on this subject, and eventually it was decided to recommend the provision of accommodation in a new building, the cost of which is estimated at £3,000, including initial equipment. It is believed that a considerable sum of money will be obtained from public authorities in respect of pathological investigations, and it is deduced that the cost of the department to the hospital might be in the neighbourhood of £800 annually during the first few years. The suggestion is made that work on the provision of this very necessary addition to the Cumberland Infirmary should be taken in hand as rapidly as possible in order that the new department may be actively operating at the time of the official opening of the new out-patients' department, the new wards, and the enlarged nurses' home.

Diathermy in Surgical Practice

In the course of a Chadwick Public Lecture delivered in the rooms of the Medical Society of London on November 21st, and repeated in the Guildhall, Bath, on November 22nd, Dr E. P. Cumberbatch, medical officer in charge of the electrical department, St Bartholomew's Hospital, gave an account of the history of physiotherapy, with special reference to medical electricity. Medical electricity, he said, was in bad repute until the end of the last century, because it was employed largely by charlatans ignorant of its mode of action, and applied to maladies in which its use was not indicated. It was now realized that electricity produced known chemical and thermal changes in the body. The galvanic current, for example, could generate chemical caustics, bringing about the destruction of small skin growths; it could cope with infection in the middle ear, etc., by introducing chemicals into them directly. The therapeutic properties of high-frequency currents were now known to be due to the

production of heat, both in the superficial and deep regions of the body. All other agents merely heated the surface of the body, but this one, used therapeutically in a technique known as diathermy, heated the tissues throughout. Diathermy was valuable in the treatment of angina pectoris, pneumonia, arthritis, and many other conditions. By its means a malignant growth could be heated until it coagulated throughout, with the result that its blood vessels were sealed and the risk of dissemination of the growth was reduced to a minimum. Cases had been reported in which, after such treatment, patients were free from recurrence for three, four, or even more years. High frequency currents were now used on occasion in place of the knife. A film-like electric arc was formed around a blunt needle used instead of a blade, and this not only divided the tissues but simultaneously sealed the small blood vessels. The advantages of such a proceeding in the removal of malignant growths was so great that a new surgery might be said to have commenced.

Ireland.

Request for Legislation on Milk Grading in the Free State

A PETITION praying for the introduction of legislation to ensure a safe milk supply in the Irish Free State has been presented to the Minister for Local Government and Public Health by representatives of the Irish Clean Milk Society. The signatories include 89 doctors and matrons of hospitals, and, in addition to urban and rural district councils, many public bodies subscribed to the petition, among them being the Cork Chamber of Commerce, the British Legion (Benevolent Department), Irish Labour Party and Trades Union Congress, Dublin Cowkeepers' and Dairymen's Association, Irish Transport and General Workers' Union, County Westmeath Committee of Agriculture, Irish Nurses' Union, Women's National Health Association, Irish Women Workers' Union, God Save the Children Fund, and St John Ambulance Brigade. The representatives of the society suggested the restriction of the use of terms designating milk, such as "Certified," "Grade A," etc., and further urged that pasteurized milk should be labelled as such until the introduction of legislation. At present those terms have no Governmental or departmental sanction, and therefore carry no guarantee as to the safety or purity of the milk. The Minister was extremely sympathetic, and gave an assurance that the report of the Inter-Departmental Committee on Milk Supply would not remain a dead letter, saying that the matters raised in the report were being fully examined by a specially appointed departmental committee, and that he hoped to receive this committee's report before Christmas. He intimated that he would receive another deputation from the Clean Milk Society in January, when he would be able to say how matters were progressing.

Salaries of the County Mayo Medical Officers

The Secretary of the Department of Local Government and Public Health, in the course of a letter to the County Mayo Board of Health, stated that he was directed by the Minister to call the attention of the Mayo Board of Health and Public Assistance to the inadequacy of the salaries of the dispensary medical officers in the county which have never been adjusted to meet in any way the increased cost of living, although other dispensary medical officers throughout the Free State have long since been accorded appropriate salaries. So far back as 1920 the inadequacy of the salaries was recognized, and on several occasions the Minister addressed the board on the matter, but without avail. The Minister feels that a point has now been reached when, in justice to the officers concerned, and in the interest of the public services for which they are responsible, steps must be taken to secure the payment of fair and reasonable salaries. He suggests that for the present a scale of £200 a year, rising by £5 a year to £300, to be applied retrospectively and to operate as from April 1st next, would meet the case, but does not propose to allow back pay at an increased salary under this scale to the

medical officers. It is suggested that the board should also review the salaries of the medical officer and surgeon of the County Hospital, and the medical officer of the County Home, and it is pointed out that the duties of those officers are particularly onerous, and that the rates at which they are paid are much lower than those enjoyed by medical men in other similar institutions. The letter states that since the agricultural grant was doubled in 1924 the contribution from the central fund, including the proportion of the agricultural grant applicable to poor relief charges, towards the expenditure on public assistance in Mayo County, is approximately one-half of the entire expenditure of the Board of Health, and that in the circumstances an improved scale of salaries for medical officers will not press unduly on the ratepayers. The department's letter was received in an unsympathetic manner by the Health Board at a recent meeting, and action was deferred pending the receipt of a return of the recorded work of the medical officers.

Correspondence.

RADIUM AND CANCER

SIR,—Few people have been more anxious than the writer that radium therapy should come into its own. This has happened, and at the present time there is a wave of enthusiasm for this line of treatment which threatens to be overwhelming, and will inevitably be followed by a reaction and much disappointment.

Unfortunately the public are already obsessed with the idea that radium will cure any case of cancer, *however far advanced*, and, moreover, they think that thousands of people are dying simply because they cannot afford radium treatment.

It is very necessary for us to keep a sense of proportion. What are the facts? First, that, as a palliative measure in a great many malignant conditions, radium is by far the best agent that we have ever had, and the way that the local condition clears up is simply astounding. Secondly, as a curative measure, many of us believe that it is superior to "excisional surgery" in malignant disease of the uterus and tongue. There is no doubt that as the technique is improved it will be used for early cases in other malignant conditions, and the curative results will be much greater. This process of improvement must, however, be somewhat slow, and so long as we entirely neglect to educate the public so that they will consult their doctors on the onset of the earliest symptoms, the percentage of cures will remain relatively small.

The medical profession is quite rightly crying out for radium, the lay press says we must have many radium centres, but all this is useless unless we can get early diagnosis and surgeons adequately trained in the use of radium. The profession and the public must demand, and get, such diagnostic facilities. The time has come when the medical profession must also spread propaganda to teach the public more about malignant disease. The opponents of such propaganda are in fear of creating cancer phobia, I venture to think that for every case of cancer phobia produced ten patients are relieved of that haunting fear, by careful education. It is a common experience of all to see quite a large number of patients who never mention their fear of cancer, but who are relieved of all their symptoms when once they know, in the course of conversation, that there is no evidence of malignant disease. Such propaganda must, of course, be done very carefully, but that it is possible, and would be of the very greatest value, I have not a shadow of doubt.—I am, etc.,

London W, Nov 23rd.

MALCOLM DONALDSON

THE DIAGNOSIS OF GASTRITIS

SIR,—In spite of Dr P J Mollov's criticisms (November 24th, p 963), I still maintain that the fractional test meal is the only safe and reliable method of diagnosing chronic gastritis. Even in the hands of the most experienced, gastroscopy is a method of diagnosis which is too dangerous and too unreliable to be of any real practical use. It

would, for example, be quite unjustifiable in a doubtful case of early carcinoma to substitute gastroscopy for the less dangerous and much more reliable exploratory laparotomy. The radiological method, which Dr Mollov saw practised in Berlin, was originally devised independently by Dr Gilbert Scott and Dr P J Briggs. It has been familiar to me for several years, and is invaluable in the investigation of cases of ulcer. But we have come to the conclusion that there are so many fallacies in using it for the diagnosis of gastritis that it is impossible to recognize that condition with any degree of certainty by means of the rays alone. The so-called gastro-mycorrhoea mentioned by Dr Mollov is, I am convinced, a myth. I have been on the look out for it for twenty-five years, and I have never seen a case.

I certainly agree with Dr Mollov that the opinions of Aschoff and von Bergmann are worthy of consideration. I think I have read everything they have written on the subject of gastric and duodenal ulcer, but I have the support of the large majority of British and American writers in my opinion that the evidence in favour of an infective origin is overwhelming. I believe that the theories of Aschoff and von Bergmann are both in part correct, but that the factors they regard as primary are really accessory, the one essential primary factor being infection. I am also quite familiar with Kalk's work on milk test meals. If Dr Mollov had read the English and American literature on the subject he would have realized that Kalk is only repeating experiments already performed in those countries by Rehniss, Crohn, Ryk, Bennett, and many others. Kalk's findings do not clash in any way with those of Freezer, Gibson, and Matthews: what they proved is that *in vitro* milk neutralizes an equal volume of 0.3 per cent hydrochloric acid. What Kalk and others before him have shown is that in the stomach milk calls forth a secretion of gastric juice. But if the milk is given hourly the juice secreted as a result of one feed is to a great extent neutralized by the milk given in the next feed. The result is that the total quantity of free acid in the stomach on hourly milk feeds is smaller than with any other diet.

Finally, I should like to suggest to Dr Mollov that an "after-cure" of British medical literature and British clinics might be a useful sequel to his visit to Berlin.—I am, etc.,

ARTHUR F HURST

New Lodge Clinic Windsor Forest Nor 23rd.

THE ETHER-URINE REACTION

SIR,—Dr Barber and Dr Oriel in their interesting and suggestive paper on biochemical investigations in allergic conditions, which was published on November 17th (p 880), describe a physical reaction between ether and urine which results in foam rigidity. On looking up my laboratory notes I find that I observed this phenomenon in 1905, and thinking that it might have some clinical significance I followed up the observation experimentally.

When 5 c cm of urine in a test tube are vigorously shaken for two minutes with 2 c cm of ether a foam structure results which is of variable durability and rigidity. The degree to which these two properties are developed varies with conditions which are only partially known, but among these are (1) the ratio of solid to water in the specimen of urine, (2) the total acidity of the urine, and (3) the ratio of ether to urine. As regards the last condition a urine which forms a rigid foam when the ether-urine ratio is 2 to 5 may fail to do so when the ratio is 5 to 5.

Addition of acid results in the lowering of surface tension, but if the acidity of the urine is high such addition is not essential. The addition of 0.5 c cm of sulphuric acid (25 per cent) effects a certain amount of hydrolysis, so that we are dealing with a chemically altered urine. A urine which fails to foam ordinarily may develop a highly rigid foam on the addition of 0.5 c cm of H₂SO₄ (25 per cent) before the shaking.

The formation of rigid foam is dependent on the colloidal state of the urine, for if the colloids of the urine

be precipitated by a 10 percent solution of phosphotungstic acid together with 5 per cent sulphuric acid, and then filtered, the filtrate when shaken with ether fails to form the rigid form. The degree of rigidity may be roughly calculated by inverting the test tube and noting the duration of time before the foam structure collapses and the superficial fluid escapes. Of course, in this estimation the quantities of urine, ether, and acid must be precisely measured, and repeated in all comparative experiments. It is also necessary to note the specific gravity of the urine whereby the ratio of solids to water may be determined.

So far I have failed to attach any definite clinical significance to this reaction. I have seen the reaction occur in normal urines in persons whom we would pass as normal. But, then, how difficult it is to decide who is normal and who is abnormal!—I am, etc.,

Liverpool Nov 21st

H JESLIE ROBERTS, M.D.

RECENT RESEARCH ON URTICARIA

SIR,—Embracing as this subject does a host of allied conditions having the same origin, upon which an inquiry into the nature of disease throws some light, I beg for a short space to show how this light helps to explain the phenomena encountered.

The clinical signs and symptoms of disease embracing urticaria and its allied conditions can be covered by the English word "shock" without having recourse to a meaningless verbiage. Shock results from the precipitation in the perivascular lymphatics, capillaries, and occasionally the arterioles and arteries, of protein particles in the plasma which have become too large or too agglutinated to continue circulating. Protein particles become increased in size by the imbibition of water, hence the use of the term "hydration" to cover this change. Protein particles become hydrated in two ways: (1) by chemical and physical agents causing a lowering of their surface tension; (2) by the adsorption of parts of other protein particles being broken up by chemical or physical agents which are sending them into true solution. Broken particles going into true solution lose water and undergo what can be termed "dehydration." Histamine, in virtue of its positively charged nitrogen atoms, happens to be one of numerous chemical substances capable of causing protein hydration, but there is no evidence that this substance, or any other chemically allied body, is the sole cause of the various manifestations of shock. The evidence is against the sole cause being such a definite chemical substance, for the main reason that hydration of some of the protein particles results from the dehydration of other protein particles. Indeed, this is the way in which most of the milder clinical manifestations of shock are produced and it explains the other phenomena, the result of dehydration, associated therewith.

When protein particles undergo hydration the various adsorbed constituents of which the protein molecule is composed become more and more part and parcel of the colloid protein complex, and in virtue of this change they lose their characteristics as simple substances. For example sugar, urea, amino nitrogen, etc., lose their identity and cannot be detected as such, hence explaining why their percentage in the blood falls. When the protein particles are subjected to dehydration the adsorbed constituents are detached from the protein nucleus and eventually find their way into solution in the liquid part of the plasma. The further the adsorbed constituents are separated from the protein nucleus the more they lose their colloid characteristics and the more identifiable they become as chemical substances, hence explaining why their percentage in the blood rises. In the severe forms of shock, where there is little or no dehydration the percentage of the adsorbed constituents in the blood falls, and this is why and how insulin causes hypoglycaemia. In the milder forms of shock, where the hydration of some of the protein particles undergoes the result of dehydration of other particles, the percentage of one or more of the adsorbed constituents may be raised. The adsorbed constituent which has its percentage raised depends upon the degree of the dehydra-

tion. That is to say, some constituents are more firmly adsorbed than others, amino nitrogen > mean > sugar > calcium > chloride. Thus it comes about that a rise in the percentage of the blood amino nitrogen denotes a more severe degree of dehydration than a rise in the percentage of the blood sugar. The constituents tend to be separated in turn from without inwards, so that when the percentage of the blood amino nitrogen is raised the percentage of the blood sugar is either normal or lowered. As the stage of dehydration precedes that of hydration, and is absent when the latter reaches its acme, the blood picture varies according to when it is made and according to the strength in quality and quantity of the intoxicants, which are generally poisonous substances of intestinal origin. In the first stage there is a rise in the percentage of the blood sugar, in the second stage a rise in the percentage of the blood urea and blood amino nitrogen, and in the third stage a fall in the percentage of all the adsorbed constituents. There is no blood picture typical of any clinical manifestation. The intoxicants may at the same time cause dehydration of the red blood corpuscles, and this may be sufficient to set free enough haemoglobin to appear in the urine, but there are no such bodies as specific lysins.

Hydrated protein particles act as dehydrators to the protein particles constituting the protoplasm of cells, and it is to this action that the urticarial wheal is due. The endothelial cells of the vessel wherein the precipitation takes place are the first cells to be attacked. This results in a dilatation of the vessel, an increased permeability of the wall, and an escape of the fluid and "solid" parts of the blood, according to varying conditions, into the tissues around, constituting what is known as oedema. Once protein particles have been subjected to these altered chemico-physical changes, the signs and symptoms resulting therefrom may be caused or aggravated by substances having no relationship to the original intoxicants. This fact explains why tests employed to detect so-called cutaneous allergy are useless, and throw no light upon the primary cause of the hydration or hypersensitiveness.

Bodies hydrated tend to become foreign in the blood, and readily find their way through the vessel walls, particularly when their permeability is increased. Some of these bodies escape through the glomeruli into the urine, and when the urine is shaken with substances insoluble in water the complex colloid substances undergo such enormous dispersion as to make in Barber and Ortel's test the ether opaque and frothy. Some years back I showed the same phenomena to occur in the cerebro-spinal fluid withdrawn from cases of parenchymatous syphilis of the central nervous system when shaken with toluene. The nuance of colours following the addition of nitric acid to urine, and the pink to violet coloration

of the hydrochloride

are indicative of the presence of hydrated colloid particles in the urine, and hence in the blood, and are tests much easier to employ.

Cardiac failure is an expression of protein hydration, hence the reason it is overcome by drugs able to break up the hydrated particles (dispersion) and to restore them to the circulation (digitalis, strophanthus camphor, ecdiazol, etc.). Hydrated protein particles have their surface electricity more under control than other particles, thereby explaining why they appear less negatively charged and more "acid." Calcium, adrenaline, etc., sometimes relieve the milder symptoms of shock, but only when they are able to cause dispersion of the hydrated protein particles, in no instances do these or still more useful drugs touch the cause of the hydration. Calcium and adrenaline function as conductors, which, generally speaking, do not cause dispersion of hydrated protein particles so efficiently as do dehydrators. It is for this reason that the dehydrator glucose is so valuable in the more severe forms of shock represented clinically by insulin hypoglycaemia, eclampsia, coma, etc. There is an association between hydration and what is known as vagotonia. Space forbids the connexion being elucidated here, but the point is mentioned to draw attention to the fact that adrenaline does not act by stimulating the sympathetic nervous system—I am, etc.,

London W 1 Nov 23rd.

J E R McDONAGH

ETIOLOGY AND TREATMENT OF PAPULAR URTICARIA

SIR,—In his article on urticaria in the *British Medical Journal*, November 17th (p. 879), Dr. Rupert Hallam states that

Papular urticaria is influenced neither by dieting nor drugs, but the patient obtains a respite if he be removed from his own environment

There is a curious factor common to all the sufferers recover immediately they are admitted to hospital, even though no treatment of any description be given. The rash returns after their discharge

These are sweeping statements, and I cannot but feel that I shall not be alone in disagreeing with Dr. Hallam.

I can recall many cases in which the elimination of an offending food, sometimes only found after prolonged investigation, has led to the disappearance of the trouble. To quote a recent case in my private practice: A male child, aged just 4 years, was brought to me last September. He presented the typical rash of papular urticaria, which the mother stated had been present for eighteen months. There was severe itching at night and the child rarely experienced an unbroken night's rest. On questioning the mother concerning the diet I found that the child was particularly fond of bananas, a fruit which I have frequently found to be an etiological factor in this disease. The only remission in the disease had been for two weeks in August of this year, during the annual holiday, when the child had not eaten this fruit. I advised the elimination of bananas from the diet. On seeing the child two weeks later the parents reported that the spots had only appeared on one occasion since the first consultation. A week ago, that is six weeks after the last consultation, the parents stated that the rash had not reappeared during this time.

In this case the cause of the trouble was discovered with fortunate rapidity, in many cases it is only discovered after keeping a food chart for some time, and after repeated trial and error. From my own experience I believe that this disorder is influenced by dieting, and that it is unnecessary to invoke the aid of some virtue which is only to be found in the atmosphere of a hospital, the absence of which from the patients' homes produces this malady—I am, etc.,

NORMAN BURGESS, M.A., M.B.,
M.R.C.P.

Clifton Bristol Nov. 21st.

DEFINITION OF DRUNKENNESS

SIR,—As one of the prime movers in 1925 who induced the Council of the British Medical Association to set up a special committee on tests for drunkenness, on which I served, may I be allowed to comment on the present discussion. Periodically the question seems to reappear in your correspondence columns and Dr. Sidney Matthews, having found himself recently in some difficulty, seeks for guidance. The advice given him does not seem to have been altogether satisfactory.

The definition adopted and recommended by this *ad hoc* committee is repeatedly referred to, but in no instance is it quoted in full, in order that your readers can form their own opinion with regard to Dr. Matthews's difficulties, it may be stated that the definition is

'That the person concerned was so much under the influence of alcohol as to have lost control of his faculties to such an extent as to render him unable to execute safely the occupation on which he was engaged at the material time'

Now, Dr. Gordon Wilson stated on November 24th (p. 964) that this definition was specially drafted to apply to the offence of being drunk in charge of a motor vehicle. As a matter of historic fact that is not so, and it is obvious that that is not so. It applies equally well, for instance—and was intended to apply—to accidents in factories or other employments, to walking on a cliff or other height, to conducting a child through or near traffic.

Dr. Matthews says, in the *crux* at issue, "the man had been drinking, but he passed every test that I could put to him, yet I knew he was not fit to drive a motor car." That is, without any applied test, Dr. Matthews was satisfied that his patient was "unable to execute safely the occupation on which he was engaged at the material time."

If that is so, then why hesitate to apply the word "drunk"?

Many seem to fail to accept what I ventured to suggest in the *British Medical Journal* several years ago, that the word "drunk" is a relative term, if this were more fully appreciated the difficulties in certain classes of cases would be cleared away. For instance, one listens to a long story of a friend recounting an action taken, and in reply one says, "You were very wise to have done so" (or not to have done so, as the case may be). But by so speaking you do not intend to convey, nor does your hearer understand, that your recounter has the wisdom of the East. If subsequently in court that roman were to be referred to no one would conclude that it had been used except in relation to the circumstances at issue at the material time.

And yet when a doctor, having first, before examination of a patient, recited for his own use or subsequently in court quoted the definition of the Association's committee, then finds it necessary to decide that the word "drunk" should be, or not be, used in regard to the case, the facts being proved, he and the court seem to boggle over the question (that is, start with fright, shy, hesitate, demur, equivocate, fumble). Why should this be so? Is it not entirely because unconsciously there has been introduced into the use of the word "drunk" a moral aspect, and one dislikes to become publicly a judge of a neighbour's morals? Had the alcohol been absorbed involuntarily this hesitancy would not arise. Is it not desirable that the medical profession should ignore the moral aspect in all cases of "being under the influence of alcohol," and confine itself to the scientific aspects of a case?

The report of the special committee is well worth re-reading, and copies can, I believe, be obtained on inquiry at the Association's headquarters, price sixpence—I am, etc.,

Hove Nov. 26th.

E. ROWLAND FOTHERGILL

SIMPLE PHLEBITIS AND EMBOLISM

SIR,—When, recently, a colleague developed a "simple phlebitis" in the calf of the left leg, the validity of the traditional treatment—three weeks in bed—came into question. I think it will be generally agreed that women who do their own housework very often suffer from slight phlebitis without lying up and without oral effects. An admittedly inadequate examination of the literature in the libraries of the Royal College of Surgeons and of the Royal Society of Medicine was not fruitful. Romanis and Mitchner (*Science and Practice of Surgery*, 1927) say: "Simple Phlebitis.—The thrombus does not become infected, and there is little or no tendency for pieces of it to soften and break loose." An ex-president of the College of Surgeons told me he had never known of a fatal embolus following a simple phlebitis.

I have heard of two fatal cases—one where an old man insisted on his cook massaging his leg, the other where the patient slapped his own thrombosed leg violently, declaring he was quite sound. I have, at the moment, under my care a lady, who, while being kept strictly in bed for phlebitis, has developed a small patch of dry pleurisy and a slight haemoptysis which suggest an infarct, but I have never heard of a fatal sequel to a patient getting up—after pain and fever have subsided—and leading an easy quiet life.

It would obviously save a great deal of nursing and worry if the three weeks with bed pans and so forth could be avoided. It would be useful if others would record their experience and give evidence which would throw light on the problem of whether there is, in fact, danger in a patient leaving his bed in such circumstances.

Northwood Nov. 12th.

O. HILTON

POSSIBLE CUMULATIVE EFFECT OF EMETINF BISMUTH IODIDE AND EMETINE PERIODIDE

SIR,—I write to inquire whether any of your readers have observed a cumulative effect from either of these two chemicals. A case just concluded in South Africa has brought out the suggestion that emetine may sometimes be eliminated in an irregularly intermittent manner.

The use of "E.B.I." and "F.P.I." in amoebic dysentery carriers has been extensive, and it will be recalled that the

Medical Research Council, as the result of an investigation, specially emphasized that large quantities of inactive bismuth iodide are essential, and total doses of not less than 30 to 40 grams, in daily doses of 3 to 4 grams, were advised.

A warning should, I think, be issued with regard to the treatment of schistosomiasis in children. Not only should the dose be carefully reduced in proportion to age, but the possibility of an accumulative effect should be safeguarded against by watching the general condition of the patient and by examining the urine with an alkaloidal reagent to see that proper elimination is proceeding.—I am, etc.,

W H MANTON

SPONTANEOUS PNEUMOTHORAX SUPERIMPOSED ON ARTIFICIAL PNEUMOTHORAX

SIR,—In your issue of November 17th (p 895) Dr S P Wilson records an interesting case of spontaneous pneumothorax occurring in a patient with artificial pneumothorax. Certain features of this case do not correspond with the typical picture presented by Hutchinson and Blair (*Tubercle*, June, 1926), as deduced from their series of seven cases. In all these cases there was a very considerable rise of temperature (in six of the cases from 103° to 105°) coincident with the onset of symptoms. In all such cases, where air is not withdrawn, there occurs a typical "staircase fall" of temperature, extending over a period which varies with the height of the initial rise.

There is no doubt that lung rupture had occurred in Dr Wilson's case in view of the x-ray evidence before and after the onset of symptoms. This would suggest that a rise in temperature, due, as Hutchinson and Blair suggest, to suddenly increased intrapleural pressure, is not a necessary manifestation of lung rupture. In view of the fact that of their seven cases two definitely developed pneumothorax, one a pleural fistula another had to undergo thoracoplasty, and two others died (cause not stated), would it not seem that pyrexia only occurs with infection of the pleura in such cases and is not a manifestation of increased pressure per se?—I am, etc.,

HUGH G GARLAND, M B, M R C S

"THE RIGHT TO PRACTISE"

SIR,—The report of Dr J Gordon Macqueen's address to the Hygiene Division, published in the *Supplement* of November 24th (p 229), contains the following concrete statement made for the information and guidance of the profession:

No degree or diploma of itself, however high it might rank in the medical or surgical world, entitled anyone to practise, the inclusion of a practitioner's name in the *Medical Register* and that alone conferred this right.

This is wholly contrary to fact and law. There is no legal inhibition upon the practice of medicine and/or surgery by any of His Majesty's subjects and registration under the Medical Acts confers no special privilege in his respect—that is, *qua* "the right to practise." As Dr Macqueen's address proceeds from one who is qualified in law as well as medicine, and thereby bears the impress of authority, I have been induced to comment on the matter.—I am, etc.,

Cambridge Wells, Nov 24th

W F HEMPHON

ULTRA-VIOLET RAY THERAPY

SIR,—I would like to know upon what evidence Professor Dixon bases his statement on October 13th (p 644) that "physicians are generally agreed that radiation by ultra-violet light is contraindicated in highly nervous and neurotic people." My own experience has been quite the reverse of this, and I regard these patients as the best subjects for the treatment.

In speaking of nerve cases I include the chorea of children, disseminated sclerosis, a myasthenic type of encephalitis lethargica, cases of menopausal neuroses which were actually borderland cases, and sent to no other means of treatment had failed, neurasthenia and the insomnia of anxiety or nerve pain. If any would be interested in the history of these cases I shall be glad

to supply the information, since it appears to me that such a statement by Professor Dixon is bound to influence physicians who have not had the opportunity of testing it. I believe that many of the nerve-racked souls at present in the various institutions would rapidly show improvement if judiciously treated by ultra-violet rays.

In regard to the irradiation of children, it is said that they react much more readily than do adults. Such has not been the case in my own practice. Nearly all the children treated by me can stand a dose which would cause a second degree erythema in almost any of my women and some of my men patients. These children will tan, but do not redden.

I should perhaps add that every one of my patients undergoes a thorough clinical examination with tests of physiological excretions in doubtful cases, and, where necessary, the treatment is combined with an appropriate internal medication to assist the good work of the mercury vapour lamp. Like Professor Dixon, I do not regard artificial sunlight as a panacea, but I think he should revise his opinion about nerve cases, so that this great class of sufferers may receive the benefit of their healing and stimulating rays.—I am, etc.,

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE House of Commons spent three days this week debating the second reading of the Local Government Bill and then considered the final resolution recommending the bill.

The Parliamentary Medical Committee met on November 27th, discussed the Local Government Bill, and adjourned in order at a subsequent date to confer with the special Committee of the British Medical Association before the committee stage of the bill begins in the House of Commons. The Committee discussed the bill's proposals on block grants and their effect on health services, particularly venereal disease services, it also discussed the proposals of the bill regarding hospitals, and opinion appeared to be generally in favour of each authority under the bill establishing a hospital subcommittee of the public health and housing committee. The Medical Committee further considered the proposal of the British Medical Association regarding transferred services under Clause 4 of the bill. This proposal would make obligatory the provision of assistance under the Public Health and Kindred Acts by virtue of the appropriate Act and not by way of poor relief. The Committee passed no resolutions.

Local Government Bill

On November 26th Mr CHAMBERLAIN moved the second reading of the Local Government Bill. Dealing with the history of the Poor Law he pointed out that in 1872 the whole country was divided up into urban and sanitary districts. The Act of that year was responsible for the origin of the medical officers of health, whose appointment was a statutory duty on those sanitary bodies. Since the Acts of 1872 and 1888 there had been no serious attempt to reform local government. Our system of local government was, in many respects, obsolete and out of date. Under the existing system there was a great deal of overlapping. From time to time Parliament had entrusted to the major local authorities the responsibility for the prevention or treatment of various diseases. There was tuberculosis, the charge of lunatics and mental defective and the great maternity and child welfare services, yet every one of those things had to be dealt with also by the guardians in the discharge of their duties. Thus there existed the remarkable and paradoxical circumstance that the question of whether a person should receive treatment at the hands of the county borough or the county council or whether he should receive it under the Poor Law from the guardians depended not upon the nature or need of his infirmities but merely upon whether he was destitute or not.

The Government had an overwhelming weight of authority in proposing to hand over to the county councils the functions of the guardians. The case did not depend merely on the easing of the financial burden, strong as it might be on that ground. It opened up a wide field for the improvement of our health services. The whole trend of practice in modern medicine and surgery was toward the treatment of many cases in institutions where there could be accumulated the specialized equipment and skill which were not always available in private homes. When the bill became law we should have a position in which there would be one single health authority in each area whose duty and function it would be to survey the whole institutional needs of that area. They would have at their disposal all the institutions now in the hands of the guardians, in many the accommodation was not fully occupied. They would have an opportunity of reclassifying their institutions of closing such as were no longer suitable for modern requirements at all, of altering and

adapting others and of using one for one purpose and another for another purpose. Even to-day there was a certain amount of classification attempted in many of the institutions of the guardians particularly in the large areas, but it must be clear to everybody that with the small opportunities that were to be found of each particular case in any one institution it was quite impossible either to get the sort of classification that they wanted or particularly to bring to it that equipment and that specially skilled staff and nursing which were essential if they were to get the best results. Only a general review over comparatively large areas and a general readaptation of buildings would suffice if a satisfactory solution of this problem was to be obtained.

Clause 4 gave power to the county borough councils and county councils to treat persons either under the Poor Law or under a number of special Acts. If they adopted those Acts for the purpose persons treated thereunder would be separated out and treated by other committees according to the nature of their ailments. The bill did not leave the county councils and county borough councils to deal with all destitute persons in future under the Poor Law as they had been dealt with in the past. The power now given to the councils was permissive and not mandatory although he was disposed to think that some day it should be made mandatory. To say that Clause 4 must be mandatory would be to put upon local authorities duties which they were not to-day capable of carrying out.

Explaining the method in which these transferred functions were to be dealt with Mr Chamberlain said it was essential that the body which provided the money should retain financial control. He had been extremely anxious to provide that as far as possible the local knowledge, the local interest and local experience that had been so valuable in the past should not be lost. In Clauses 3 to 7 provisions were set out which showed how they were going to try to combine central financial control with the fullest possible use of this local knowledge. It would be the duty of every county council and county borough to prepare an administrative scheme. In that scheme they were to appoint a Public Assistance Committee. This was not necessarily a new committee, it might be one of the existing committees of the council. To that committee in the first instance, the council would refer these transferred functions and it would receive the recommendations of the committee as to how they were to be dealt with. Of that committee two-thirds must be members of the council and the remaining one-third might be co-opted among the co-opted members must also be women. Clause 6 stated that each county must under its scheme divide up its area into a number of smaller areas each of these comprising one or more county districts. In each of these areas there had to be set up a subcommittee of the Public Assistance Committee specially designed to carry on as far as possible the duties of the old boards of guardians where it was compatible with the new financial arrangements. The subcommittees were to be called guardians committees, and it was hoped that members of them would continue to call themselves and to be called by other people guardians. Two-thirds of the guardians committees would be elected members and there would be a considerable number of actual members of the old boards who would become members of the new guardians committees. There would also be co-opted members which again must include women. The duties of these committees included the examination of applications for relief and the determination not only of the amount but the nature of the relief they would determine whether the applicant should or should not be admitted to an institution and they were not excluded from visiting inspecting and even managing any Poor Law institution if the Public Assistance Committee thought fit.

Clause 13 provided for the recovery of expenses. Under the existing law it was the duty of guardians to recover either the whole or part of the cost of relief from any person maintained in these institutions. It was not the law that the local authority must do it although some of them did, and he thought in the case of maternity homes they always did so. But, obviously if the functions of the guardians were to be transferred to the council they must not have a situation in which one person who happened to be destitute would have the cost of relief demanded from him while another person, not destitute who went into an institution of his own accord did not. There must be one rule for both and so the bill provided that the local authority would have the duty imposed on it of recovering such part of the cost of maintenance in an institution as an inmate could afford. But they excepted in that provision the case of an infectious hospital where persons went in for the good of a community and that also included the case of the tuberculosis sanatorium.

He saw from the amendment paper that this was taken as involving some danger to the maternity services. At present he did not see how that could be the case. It was the general practice of local authorities to make charges for institutional relief and seeing that a woman who had her confinement in an institution was relieved of the cost of a doctor or midwife, and that she had in most cases the maternity benefit secured to her it was difficult to understand why she should not be asked to make some contribution to the cost of her maintenance in the institution. He would only say that he had an open mind on the subject. He was anxious that nothing should be done that would in any way hamper or check the development of the maternity services to which he attached the utmost importance. If he could be convinced during the committee stage of the bill that this provision would have that effect or that any amendment could usefully be inserted which would still further protect the maternity services he would receive any such suggestion with respectful consideration. Clause 15 applied to London the provisions which applied to the counties in general with the necessary adaptations. The Metropolitan Asylums Board and the Metropolitan Common Fund would

disappear. The functions of boards of guardians were handed over to the London County Council, and the London County Council was left to make its own arrangements for the administration of the law through subcommittees. Part II of the bill dealt with registration services when the guardians disappeared their functions would be handed over to the counties and county boroughs. Registrars would be placed on a salary basis instead of being paid by fees.

Dealing with highways and road making Mr Chamberlain said that the question of town planning was bound up with the design and alignment of roads. Provision was made for the inclusion of the county councils in joint town planning committees with other local authorities.

A number of clauses followed which were all in accordance with the recommendations of the Onslow Royal Commission. Clause 45 provided that the county council might, out of the county rates, make a contribution towards the expenses of a rural district for the purpose of improving sewerage or water supply. Clause 48 was designed to bring together education authorities and maternity and child welfare authorities. It was provided that the maternity and child welfare services might be handed over to the authority which was also the education authority so that continuous supervision might be exercised over the health of the child. Clause 50 dealt with the supervision of midwives, Clause 51 with the review of accommodation for infectious diseases in counties and Clause 52 authorized the delegation of certain functions from the London County Council to the metropolitan borough councils.

Turning to the finance of the bill Mr Chamberlain said that the Government's plan was that national contributions to local services should be distributed not in accordance with what the local authorities spent but with their needs including of course their relative ability to pay. De-rating took away a large existing source of revenue of the local authorities and replaced it with a larger sum. That sum instead of being a percentage grant based on something received twenty thirty or forty years ago would be based on needs reviewed from time to time. The block grant was to be recalculated every five years and the amount was to be fixed for each year in any period of five years. The distribution among the counties and county boroughs was first to be partly and ultimately entirely made according to a formula. The result he anticipated would be that each local authority would be secured resources adequate, not merely to carry on the services as they were to-day but to allow for reasonable expansion in accordance with the public conscience and the demands which the increasing revenues of the country would permit.

He had been very much astonished at suggestions which had been made that the system of block grants would injure or even starve the health services and especially the maternity and child welfare services. If he thought for a moment that that would be so he would never allow it to go through but he was convinced that those fears were utterly groundless. Leaving out of account three or four wealthy towns which had an exceptionally high expenditure on these services the average grant received by the authorities throughout the country in respect of maternity and child welfare was about 5d per head of the population. He took as instances one or two towns under the average which were therefore not receiving the average maternity and child welfare service. Oxford, a comparatively wealthy place with nearly £8 10s rateable value per head of the population had a maternity and child welfare grant of 4d. Under the new scheme its grant in the first five-year period would be 26d and the final grant, when the full formula came into operation, would be 31d per head. In an entirely different case that of Merthyr whose rateable value was only £2 6s per head the maternity and child welfare grant was now 4d. The grant in the first quinquennium would be 73d per head, and finally 108d. In Tynemouth where there was special need the rateable value was £4 1s and the maternity and child welfare grant was 38d, the gain in the first quinquennium would be 162d, and when the scheme became fully operative 206d per head.

Comparing these figures of the grant per head with the amount spent to-day on maternity and child welfare service which on the average for the whole country was 5d per head it was perfectly clear that the formula would give ample resources to every locality to deal with this service and to multiply it many times over. There could not be any question about the adequacy of the amount available it was not an expensive service and it did not take much money to produce considerable results. He had taken much trouble to protect it in the bill. Clause 75 provided that in the county districts voluntary associations would receive, in addition to the population grant an increased grant to enable them to carry on the service. Again under Clause 83 the voluntary associations were protected because the schemes to be prepared by local authorities showing the contribution to be given to them must meet with the approval of the Minister who had the final say as to what the contribution might be. Under Clause 86 the Minister had power—such as he had never before held—to take away the grant or that portion of the grant which he might think right from any local authority which failed to maintain this service adequately. If in the committee stage it could be shown that the clause gave insufficient protection to this service he would consider any amendments which might be put forward. There was no service to which he attached more importance and in which he took a greater interest than maternity and child welfare and he was not going to allow any consideration to interfere with its fullest possible development.

The needs of areas in accordance with which the national contributions would be distributed would be measured by an ingenious and carefully worked out formula which would be found in the fourth schedule of the bill. Obviously the popula-

tion was the principal factor which governed the need of a locality, but it was not the entire measure of the need. They had also to take into account the relative wealth and poverty of different districts, and so rateable value per head and number of children under 5 were used to weight the population. They would find a larger proportion of children in the poorer districts and it would not do to rely only on rateable value as a measure of the relative wealth and poverty.

Having dealt at length with the financial provisions, Mr. Chamberlain concluded by prophesying that the scheme though it might well be altered in details in its passage through the House would in its main outlines still hold the field, and that it would prove to be a courageous, comprehensive, and successful attempt to remove anomalies and injustices which had too long been allowed to impair and weaken the magnificent structure of local government.

Mr. A. GREENWOOD moved the rejection of the bill on the grounds among others that it would perpetuate the evils of the Poor Law system and would arrest the normal and steady development of local health services by the establishment of fixed block grants from the Exchequer by the imposition of a charge for treatment in hospitals especially maternity hospitals, which was calculated to increase the already high mortality among mothers. He contended that to combine roads and public health in a block grant was an absurdity. The block grant was a Treasury device for saving money to the Exchequer, because it meant the spending of less by the Government on local government services. The Government was allowing the spirit of the Poor Law to pervade the whole of local government. Their proposals would injure the health services of the country. Health authorities would be in the position of having to make inquiries and ascertainsments and to collect money when they should be fighting out disease, that would reduce medical officers to debt collectors.

Dr. FREMANTLE said that in the amendment of the Labour party, and in that on the paper in the name of the Liberal party, it was suggested that the gravamen of the case against the bill was the injury that would be done to the health services. The amendment before the House said that the bill would arrest the normal and steady development of local health services and would increase the already high mortality among mothers. It was a challenge which must be met. When he read the bill he felt that it was a measure in regard to which they would have the general sympathy of those members of the Opposition who worked with Mr. Greenwood for the improvement of the health services. Here was a measure that was fulfilling a large number of the great objects which had been put forward in several Royal Commissions, and above all in the Royal Commission on the Poor Law—a measure it seemed to him in which they could gladly co-operate—at least in so far as the health service section was concerned—for the common cause and obtain amendments. He wished to call attention to the most authoritative announcement that had yet been made by the medical profession. It had only recently been put into his hand, and he had had no share in preparing it. It was the considered statement of the British Medical Association Poor Law Reform Committee. The Committee sat for a long time on the subject, and their general conclusion was. Resolved that the Council be recommended to express its approval of the Local Government Bill 1928, in so far as it attempts to secure unification of the medical services of the country. The bill was discussed under three main categories: first machinery of local administration; secondly the effect of the bill on medical officers of health and Poor Law medical officers; and thirdly the effect of the finances of the bill on the health services. After endorsing the measure under these several heads in which they were particularly concerned, the Committee proceeded to suggest certain alterations, modifications, and amendments which could be produced in committee and which would be put forward in due course. He hoped that members in all parts of the House would combine with him in helping to get amendments accepted further to improve the machinery of the bill.

Being himself a medical officer of health for a county area in which these matters were constantly to the fore, who for a period of twelve or fourteen years had had to consider work and report upon the complications which this measure hoped to simplify, he wished to state that in the course of those many years, county medical officers of health had always felt the hopeless confusion of authority which existed between the different bodies dealing with health and that in every way the work of public health had been crippled because of this complexity. There was no relation between the Poor Law authorities whether in their relief services and their institutional services and the sanitary authorities. There was no real combination between the sanitary authority on the one hand and the county authority on the other. The only powers that the county authority had over the sanitary authority was occasionally to report to the Local Government Board as it formerly was or to the Ministry of Health as it now was cases in which the sanitary authority was in default and it appeared that the Ministry might take certain action. One of the most crying needs was for some kind of co-ordination among the different authorities. The bill met that need in a way that exceeded any proposals that had been made hitherto and the fact that had been alleged against it that it was a combination of different measures was from this point of view clearly in its favour. It was taking the opportunity to bring together an enormous number of these different services in order to make a big move, a big change, and a big reform—indeed more than a reform for it was an absolute revolution of local government. One point on which obviously members on the opposite side must be agreed was that there was a measure of co-ordination and a revolution that was essential for the public health service. The bill gave power to the county authorities to establish definite

relations with the sanitary authorities responsible for hospitals, and at the same time to use the institutions of the Poor Law for combined purposes. There was the possibility of co-ordinating the whole of the former hospital services of the country, which was of enormous advantage in regard to the cause of infection, and which might lead to economy. At the same time, they might secure much more efficient services and more efficient institutions for the patient.

Another point which required co-ordination, and which had not been mentioned that evening—it was not mentioned by the Minister of Health in his opening speech—was the question of mental hospitals and mental deficiency institutions. A very large amount of work in regard to dementia was the concern of the Poor Law and the Poor Law institutions, and a large amount of work in regard to the question of mental asylums, mental hospitals, and mental deficiency came under the county councils. Under this bill they had the possibility of co-ordinating this work and the county councils would be able to deal with the mental ailments, dementia, and mental deficiency as one undivided authority for the whole county area.

They did not intend to give, continued Dr. Fremantle, and he certainly could not as a medical officer give unstinted adherence to the bill without suggesting the necessity for considering the need for amendments. He had listened with gravity and anxiety to the suggestions that had been made against the bill from the point of view of those who were concerned with maternity and child welfare services. It was quite true that those were developing services, and were a great essential need of the country. They were administered largely by voluntary effort, and it was certain that many of those concerned with the services were seriously alarmed as to the possibilities of danger from the operation of the block grant. The Minister of Health had said that the last thing he intended was to hinder the maternity and child welfare services in any way, and he had put into three clauses definite provisions for easing their situation. Dr. Fremantle hoped that still further security would be given. He was not at all sure, although he believed in the block grant system in the long run for the sake of the eventual good to local government, that the time was ripe to apply it at once to the maternity and child welfare services, and it might be advisable and possible to give a little longer time—say, for the first quinquennium—under the present system while the voluntary associations were making the adjustments necessary to enable them to work the new system proposed.

In regard to the much debated subject of the local supervising authority under the Midwives Act, a further reservation had to be made in regard to co-ordination. It was a difficult subject and obviously it would be better theoretically if the Act could be administered by the same authority which administered the Maternity and Child Welfare and other Acts. But the difficulty was that midwives and those associated with them felt strongly that the only authority capable of securing the proper experience and the proper inspection of midwives was the county authority. There were minor exceptions, and it was hoped, in regard to any rate, to that aspect of the midwives service, that the responsibility which was given by this bill to the Minister of Health to approve or not approve the transfer might be most carefully used.

He had shown that the Poor Law Reform Committee of the British Medical Association approved the bill in its attempt to secure unification of the medical services of the country. With regard to that, there were two reservations which should be mentioned and which were capable of adjustment he hoped, in committee. The first was in regard to the distribution of Poor Law functions under Clause 4. This clause provided that the Poor Law functions might be distributed in regard to health services among the committees of the county councils or county borough councils which dealt already with education and public health Acts, the Maternity and Child Welfare Act and so forth. But it used the word "may." That gave authorities the option of transferring these functions to the new guardians subcommittees which would make confusion worse confounded. It would perpetuate the present position, which would be right against the report of the Poor Law Commission which this bill practically proposed to carry out. Members on all sides of the House who had been keen on public health development were even keener on the proper distribution of functions and the British Medical Association and the medical officers of health were combined in saying that they wanted each committee of the county councils and county borough councils to be responsible for the whole sphere of service quite independently of the separate individuals or class of individuals with which they were dealing.

The question of the hospitals was a most difficult and thorny one. There was naturally a great feeling on all sides who were keen upon the voluntary hospitals—and all that they meant—regarding the competition which might be set up between the voluntary hospitals and the municipal hospitals. The best arrangement for overcoming this difficulty was by mutual understanding and co-operation and it was strongly suggested by the British Medical Association—and he backed the suggestion—that the county and county borough councils should be required to set up hospital subcommittees who would be able to advise them regarding the efficient management of the hospitals and effect co-operation with the voluntary hospitals. Some regret might be expressed that the Lunacy Acts were left out of Clause 4. The reason for this omission was that it was intended to deal with those Acts in pursuance of the report of the Royal Commission. They had pressed for that for a long time and he hoped that it would be carried out in the next Parliament. He noted with satisfaction the co-ordination of the medical officer of health services as a step in the direction of the further increase of whole time medical officers of health, he was however at loggerheads with the Minister of Health in regard to the rural areas. He maintained that they could not say that one system was ideal rather than

another, and the suggestion that the only way to deal with rural areas was by whole time medical officers who did not engage in private practice was, in his opinion, wrong. What was wanted in rural areas were men of the best character, with the best opportunity to carry out the work. There were obvious exceptions, but there must be some latitude allowed.

Lastly, he hoped that some further progress might be made in separating the health services from the system of relief. That had been the cardinal policy of the medical profession all along. It was a very difficult question, and he still thought that those who could afford to pay ought to do so and that the public services ought not to be abused. But, on the other hand, they had the precedent of the Infectious Diseases Acts, and he hoped that by degrees as these municipal health services developed under this new arrangement, the strictly health services might be considered as extra services and separate from relief. He challenged the Opposition parties in regard to their denial of the value of this bill to public health. The future of the measure must depend upon the backing given to it in the country. For that purpose they wanted publicity above all things. The best way to secure publicity for the bill was through the B.B.C., and he urged the Government to arrange that speeches, representing all parties, should be broadcast. If that were done, he believed that the country would be immensely enlightened regarding this bill which might be rightly called the Magna Charta of public health and local government.

The debate continued until the evening of November 28th, when the House divided.

Replying to a question on November 26th Sir Kingsley Wood said he did not anticipate that any permanent addition to the staff of the Ministry of Health would be necessary in the event of the Local Government Bill becoming law. Work incidental to the inception of the scheme would involve some temporary addition to the staff, and the consequential expense was estimated at £50,000.

Preservation of Infant Life Bill

LORD DARLING, in the House of Lords, on November 22nd, moved the second reading of the Preservation of Infant Life Bill designed to prevent children being destroyed at birth. This bill passed through the Lords last session but failed to obtain support in the House of Commons after its title had been changed to the Child Destruction Bill. Lord Darling now said that one of His Majesty's judges had drawn his attention to the number of cases where no punishment could be awarded to a person for the killing of an infant during birth because the killing was neither murder nor abortion. The bill was in the form in which it left a Select Committee of the House of Lords last year.

LORD ATKIN said this gap in the criminal law had been recognized by many generations of justices. The bill in its present form was not a satisfactory piece of legislation. The practical effect of making an offence of the killing of a child during birth by the mother would be very small. It would be difficult to persuade a jury that a woman ought to be held criminally responsible for an act done in the pangs of an unintended, uncaused, and possibly difficult labour. The bill applied to third persons, to doctors and to midwives, and raised the position of the doctor who had to consider during delivery whether to save the life of the mother or that of the child. Under the bill such a doctor committed a criminal offence unless he proved that he acted in good faith and that his action was needed to save the mother's life. He objected to creating crimes by legislation and throwing on anyone the onus of proving that he was innocent. Doctors had been harassed quite enough by legislation, and should not have to consider whether a disappointed parent or a mischievous attendant would charge them with this offence. The provision of the bill making it an offence to kill a child in the mother's body more than twenty-six weeks after conception was unnecessary, because it was impossible to do so without procuring, or attempting to procure a miscarriage.

LORD DAWSON associated himself with Lord Atkin's arguments. The House should not be too anxious to fill this gap in the law. It was a good thing in many cases if the law turned a blind eye to this offence by unmarried mothers committed after months of anxiety often culminating in difficult labour. These girls, in many cases did not require legal conviction but the hand of understanding and fellowship. If he were a professional man who had knowledge of an act of this kind and satisfied himself it had been done under stress of impulse and anxiety, he should not consider it part of his duty to divulge the fact to the powers that be. The bill would inflict a hardship on men in the profession to which he belonged and on midwives. It threw on them the onus of proving that they were not committing a crime. It would go far to inhibit them and discourage them from doing their work. In fairness and justice to the doctor and in the interest of the community he urged the Lords to reject the bill.

LORD RUSSELL concurred in these arguments. LORD HAILSHAM said Mr. Justice Talbot in a charge to a grand jury had pointed out the gap in the law and had said. The result of the law is that a fully born child in many cases can be destroyed with impunity and I do not think it very creditable to our legislature that the defect in the law should be left unremedied. Lord Hailsham said he shared this view. He did not think anyone contemplated that a distraught mother should be punished if she killed her child before it was fully born any more than in similar circumstances just after it had been born. Such circumstances were always taken into account in the modern courts. He agreed that it was most important to safeguard the position of the doctor and the midwife. Largely because of representations

by Lord Dawson on that point the original bill had been sent to a select committee, on which Lord Dawson served. Whether the exact phraseology of the bill was sufficient to safeguard the profession might be considered again by a select committee or by the House of Lords in committee. As he read the bill, although, in fact, a doctor was mistaken in thinking it necessary to kill the child in preserving the life of the mother yet so long as he acted in the honest belief that the necessity existed he would not be under any liability. Since Lord Atkin felt no doubt on that point it ought to be made clear in committee. LORD ATKIN said he was content that the bill should be examined in committee.

The bill was then read a second time.

Protection of Animals (Amendment) Bill

In the House of Lords, on November 22nd, LORD BANBURY moved the second reading of the Protection of Animals (Amendment) Bill. He explained that this short bill proposed that any owner of a dog found guilty of cruelty to the animal might, in addition to any other punishment he deserved from receiving a licence to keep a dog or dogs.

LORD DAWSON OF PENN pointed out that the original Act contained no definition of cruelty. In view of recent controversies on what constituted cruelty in experiments on animals, Lord Dawson suggested that Lord Banbury should amend his bill by inserting a definition of cruelty as 'pain inflicted wantonly and needlessly.'

LORD DESBOROUGH speaking for the Government, thought the proposal of the bill impossible to carry out. An applicant could go to any one of 12,000 money-order offices and take out a dog licence. The Government would not oppose the second reading of the bill but could not offer facilities to the measure in its present form.

LORD BANBURY, replying to Lord Dawson's suggestion said he had specially drafted the bill so that the House should not go into other questions such as what constituted cruelty.

LORD DESBOROUGH remarked that 3,000,000 dog licences had been taken out last year.

The bill was read a second time.

National Health Insurance.

Definition of a Spinal.—DR. VERNON DAVIES asked Mr. Chamberlain on November 22nd to state his reason for deciding under the National Health Insurance Regulations that a spinal jacket required for the treatment of tuberculosis of the spine was regarded as a spinal but that a spinal jacket required for the treatment of lateral curvature of the spine which was often due to tuberculosis, was not a spinal, and therefore could not be supplied to insured persons. MR. CHAMBERLAIN said the reason why a different view was taken with respect to the appliances was that he had to look not to the name given to an appliance but to the precise object which it was intended to serve. He had invited the Insurance Acts Committee of the British Medical Association to discuss with the Ministry the difficulties of defining spinals for the purposes of medical benefit. MR. EVANS asked whether Mr. Chamberlain knew that many osteopaths cured curvature of the spine without any appliances.

Bills

Young Persons in Offices.—On the motion of Miss WILKINSON the House of Commons on November 21st gave a first reading to an Offices Regulation Bill 'to regulate offices and the employment of young persons therein.' Introducing the bill Miss Wilkinson said no protection, except the local sanitary by-laws covered workers in offices. They were outside factory legislation and the Shops Acts. The grievances were growing worse with the overcrowding in great cities. Women were entering offices where the sanitary conditions were doubtful even for men and inadequate for women. In some recently built offices there was no ventilation. In one of the most modern buildings in Regent Street the office was underground and artificial light was necessary all day. One girl there had been warned by a doctor that she was in danger of contracting pernicious anaemia if she continued to work underground. The bill recognized that it was not possible to reconstruct all offices in a year. It gave wide powers to local authorities and put the onus on the owner.

MR. WARDLAW MILNE secured a first reading on November 21st for a bill making it obligatory for owners of motor vehicles to be insured against third party risks.

Post-race Encephalitis.—MR. CHAMBERLAIN stated, on November 21st that of the five cases of post-race encephalitis (four fatal) mentioned on page 145 of the Rolleston Committee's report four were vaccinated with Government lymph and one was not. In the latter case and three of the former death occurred.

Nurses and the Midwives Acts Committee.—Asked, on November 22nd by Mr. Kelly why the profession of nursing had been refused representation on the Departmental Committee appointed to consider the working of the Midwives Acts 1902 to 1916, MR. CHAMBERLAIN said he did not consider it necessary to appoint a registered nurse on this Committee as the various nursing organizations could give evidence before it. Only one of these organizations declined to avail itself of this opportunity.

Obituary

SIR HECTOR CLARE CAMERON, M D, F R C S, C B L,

Dean of Faculties and Emeritus Professor of Clinical Surgery in the University of Glasgow

We have to record with great regret the death of Sir Hector Clare Cameron, the famous Scottish surgeon, which took place in his eighty-sixth year, on November 22nd, at his home in Woodside Crescent, Glasgow.

Sir Hector Cameron was born in Dumfries, British Guiana, on September 30th, 1843. He was the second son of Donald Cameron, sugar planter. Sent home for his education, he first went to Madras College, St Andrews, and afterwards was a student in the Arts classes of the ancient University of that city.

His medical education began in Edinburgh University, but the greater part of his course was taken in the University of Glasgow, where Joseph Lister was then Professor of Surgery. He graduated M B, C M in 1866 and M D in 1868. In the latter year he became assistant to Lister at the Royal Infirmary. The association then began and deepened throughout his life, and although two years later Lister was transferred to Edinburgh, Cameron, who despite many inducements to move eastwards with his chief, had decided to remain in Glasgow, became one of the leading propagandists of the young, antiseptic school, and continued both in precept and practice to develop and spread the doctrines of his master. At the early age of 32 he was appointed surgeon to the Royal Infirmary, resigning this post in 1871, when he obtained a similar position in the Western Infirmary. In 1900, on the retirement of Dr George Buchanan from the chair of clinical surgery in Glasgow University, Cameron was elected by the University Court, without advertisement to that chair, which he occupied until 1910. He held from time to time many other appointments—surgeon to the Royal Hospital for Sick Children, consulting surgeon to the Glasgow Royal Asylum, surgeon to the Eye Infirmary and to the Lock Hospital. For many years he was a member of the University Court as a representative of the senate, and of the General Medical Council as representing the Royal Faculty of Physicians and Surgeons of Glasgow. He held examinations in the Universities of Cambridge and Aberdeen. Such offices as his professional brethren could confer on him he also occupied with unanimous assent—among them the presidencies of the Royal Faculty of Physicians and Surgeons, the Pathological and Clinical Society and the Royal Medico-Chirurgical Society of Glasgow. At the meeting of the British Medical Association in Toronto in 1906 he was president of the Surgical Section. During the war he became Red Cross commissioner for the Western District of Scotland, and since 1920 he acted as convener of the Ralston Red Cross Hospital. He was also dean of faculties in the University of Glasgow, and was appointed by the General Medical Council to supervise the examination in medicine conducted by the medical schools of Great Britain and Ireland.

These numerous services received signal marks of national and academic approval. He was knighted by Queen Victoria in 1900, in 1911 the University of St Andrews made him an honorary F R C S, in the following year his own university conferred the like honour, and after the war he was created C B L.

His contributions to medical literature were not numerous, but between 1870 and 1884 articles from his pen appeared occasionally in medical journals and transactions, on such subjects as ophthalmology, tracheotomy, foreign bodies in the air passages, trephining, etc. At wider intervals in later years he wrote upon such questions as the treatment of hip joint disease, and on the analogy of cutaneous cancer and tuberculosis. He was the author of valuable papers and addresses on Lister and his work, in particular the Dr James Watt Lectures on the evolution of wound treatment during the last forty years published as a book in 1907. This is a historical and documented account of the origin and development of antiseptic surgery, and bears the imprimatur of Lister himself, thus contributing a definitive record of the great surgeon's system and ideas.

The relative paucity of his publications was due principally to the fact that his bent was clinical rather than scientific. As has already been indicated, he began his professional life as a disciple of Lister. When his master left him the fallen mantle of apostleship descended upon him, and for the rest of his life he was content by voice and hand to expound and illustrate the truth of the new surgical learning. His opportunities for original research and writings were also restricted by the great and steadily growing pressure of private work. As an operating surgeon his reputation was not exceeded by that of any contemporary. The social standing of his patients

SIR HECTOR CLARE CAMERON

made no limit to his sense of duty. He was pre-eminently accessible to the less fortunate, and countless instances are on record of his generous and unsparing beneficence to the needy and humble who sought his services. As a teacher he was always popular, alike in his Societies and his didactic moods. An interesting expositor, he avoided set orations, and his lectures were replete with the results of his own experience, and illustrated with historical parallels and allusions. And likewise as operator he was methodical, calm, and self-reliant. Conservative in his outlook, he distrusted sensation and "brilliance" in surgery. "Gentlemen," he would say, "you must not make your light shine at a patient's cost." Or again, "To open an abdomen without a constructive diagnosis is the height of surgical curiosity." In his wards, theatre and lecture room, his students never failed to realize the deep human sympathy that informed all his work. "Il n'y a pas de maladies, il n'y a que de malades" was the motif of ethical discourse or ward visit. His belief in Listerian antiseptics, as distinguished from the illogically termed "aseptic system," remained unshaken to the end of his hospital term, and when, during the war, the foul infectious of the soil of

made no limit to his sense of duty. He was pre-eminently accessible to the less fortunate, and countless instances are on record of his generous and unsparing beneficence to the needy and humble who sought his services. As a teacher he was always popular, alike in his Societies and his didactic moods. An interesting expositor, he avoided set orations, and his lectures were replete with the results of his own experience, and illustrated with historical parallels and allusions. And likewise as operator he was methodical, calm, and self-reliant. Conservative in his outlook, he distrusted sensation and "brilliance" in surgery. "Gentlemen," he would say, "you must not make your light shine at a patient's cost." Or again, "To open an abdomen without a constructive diagnosis is the height of surgical curiosity." In his wards, theatre and lecture room, his students never failed to realize the deep human sympathy that informed all his work. "Il n'y a pas de maladies, il n'y a que de malades" was the motif of ethical discourse or ward visit. His belief in Listerian antiseptics, as distinguished from the illogically termed "aseptic system," remained unshaken to the end of his hospital term, and when, during the war, the foul infectious of the soil of

Thandlers reproduced in casualty clearing stations and base hospitals the horrors of pre-antiseptic surgery, and necessitated a revival of some post-Listerian modes of treatment, his gratification over the vindication of the older system was not concealed.

He retired from the clinical chair and from active surgical practice in 1910. This event was one of the severest ordeals of his life. When contemplating his imminent resignation he wrote in a private letter:

Dr Quincey in the *Confessions* quotes a passage from Dr Johnson and he says that it is the only feeling remark that Dr Johnson ever made. It is this: "No one ever did anything consciously for the last time of those things which he has been long in the habit of doing without sadness of heart. The sentiment is a feeling one because it is so truly natural and human. When I therefore some day soon realize that I am making my last hospital visit (I have been making them for thirty-six years—since 1874) I know I shall feel sad and indeed. The mere anticipation weighs on my spirits."

On the occasion of this retirement he was entertained to dinner by fifty of his former assistants and house-surgeons, and presented with a loving cup which bore the inscription—

H C C
Magistro carissimo Discipuli
MCMX

No memoir, however brief of Hector Cameron's life would be adequate did it not include a reference to the richness of his mind and the graces of his personality. In youth he had absorbed much of the spirit of the ancient classics and of the great works of English literature. In later years his retentive memory furnished him with many an apt allusion and quotation. He had an Augustan love of the Latin tag and the polished phrase, *le mot juste* had an ineluctable attraction. Unrivalled as a raconteur, he was delightful in social converse, and his correspondence provided many characteristic examples of the vanishing art of letter-writing. Outside of his scholarly interests fishing and shooting were his favoured recreations, and in both sports he excelled.

But to all who knew him the most abiding memory will be that of his almost old-world courtesy and graciousness. If in his public duties he ensued compromise more than controversy, it was because of his broad humanity, his catholicity of spirit, and his innate kindness of heart. Alike as teacher, surgeon, colleague, administrator, and man of the world, he earned the respect and admiration of his associates, and, what is more rarely vouchsafed to outstanding men, the deeper homage of affection from his friends. His fine features, crowned for many years with a wealth of silvery hair, marked him out on any platform or in any society. Two eminent artists—Henry and Greiffenhagen—have painted the outward semblance, but no material portraiture will presore to future generations the real picture of nobility and charm that is treasured by those who know him best.

J F

Sir Hector Cameron married a daughter of Mr. William Hamilton Macdonald, who predeceased him in 1879. He is survived by a daughter and two sons—Colonel Donald Cameron of the Army Service Corps Staff College, and Dr. Hector Charles Cameron of Guy's Hospital.

We are indebted to Sir Donald MacAlister, Bt, President of the General Medical Council, Principal and Vice-Chancellor of the University of Glasgow, for the following tribute:

May I repeat here, what I felt moved to say in my presidential address to the General Medical Council this week, concerning Sir Hector Clare Cameron? I announced that last week that veteran died, full of years and honour at the age of 85. One of the last survivors of Lord Lister's personal assistants and coadjutors—he has fifth been described as Lister's "beloved disciple"—he held a high place, not only among Glasgow celebrities, but in the affectionate regard of the surgeons of the world. "To myself his loss is irreparable, for from time to time when, in 1889 he first welcomed me to this Council as a colleague, until the end he was my unfailing friend and counsellor, on whose kindly wisdom and manifold experience it was

ever my privilege to draw." To the Medical School and to the University of Glasgow he was a pillar of strength, revered and beloved for his unselfish interest in, and devotion to, their well-being. Lamented alike as teacher, as surgeon, as administrator, and as benefactor, he had a unique place in their regard. In testimony may be cited the honorary offices he held—as consulting surgeon to several of Glasgow's great infirmaries, his presidency of the Royal Faculty of Physicians and Surgeons, his dignified place, to which he was elected and re-elected as Dean of Faculties in the University, his membership of its University Court and Senate, and many others, heaped upon him by bodies and institutions which he had nobly served, or which desired to derive honour from association with his honoured name. His warmly affectionate nature, his ready helpfulness, his freedom from any trace of self-seeking, his transparent honesty of purpose, and the immediate impression of deep sagacity and practical wisdom which he conveyed, made him a very Nestor among us, and a Nestor loved and admired beyond others. His loyalty to Lister, his cherishing and setting forth of the valued memorials of his master which he possessed in rich abundance and his broad and cultured utterance on all occasions of ceremony, will long be remembered in Scotland. With him a great representative of a great generation passes away, and some of us cannot but feel that no one quite fitted to take his place is left to us.

Mr. G. H. Edington, D.Sc., M.D., Lecturer on Clinical Surgery at the University of Glasgow, writes:

By the death of Sir Hector C. Cameron the community of Glasgow mourns one of her most prominent citizens, and the Medical School one who in the days of his active professional work occupied a foremost position in the ranks of surgery. I was privileged to receive my early training in his wards, and later to be associated with him in his work, and his death now severs a friendship which remained unbroken for a period of over thirty years.

As a teacher he had the gift of presenting problems to his students couched in language which, enriched by happy simile and apt metaphor, fixed itself in their memories. His description of the ailments of the patients brought to their notice was illustrated by examples drawn from his wide clinical experience and likewise from his reading in the literature of the subject. His operations were carried out with a meticulous attention to detail which was in itself a liberal education for the onlookers. There were, however, taught in his clinic things which were outside the mere bones of clinical surgery. He, by his example, taught us veracity, concern for the best interest of the patient, care for the feelings of others, and a warm and broad humanity. The humblest patient in his wards received the same consideration as any of his cases in private and it was no uncommon occurrence for him to return to the hospital in the afternoon to see how those on whom he had operated in the morning were progressing, while very rarely did he miss paying a Sunday visit. He was a pattern of dignity and modesty, never thrust himself forward, never cried his wares in the market-place. We junior students took it I am afraid, as a matter of course, and the degree of his modesty and his professional skill only became known to us when we moved to other clinics and saw very different post-operative results. We failed not then to draw a comparison, and were struck by our late chief's merits, and his equally marked unobtrusiveness. When later I came to enjoy his friendship and to talk with him in his home circle I was able to appreciate that I was in the presence of one who was not only a surgeon, but a man of wide education and wide interests. He was a keen lover of sport, and during his vacations he enjoyed shooting, fishing, and golf. He was keenly interested in birds, and delighted to draw attention to their various notes. He had a well stored memory, and freely drew on it for anecdotes and quotations apropos whatever subject might be under discussion.

When, as they did, honours came to him they were fully appreciated. He never vaunted them. They were all unsought, and were conferred on him in recognition of good work well done, and they gave pleasure to his many

friends and to his even more numerous patients. His attitude to honours was fittingly summed up in a brief note which he received from an old Scottish lady, a former patient, on the occasion of his knighthood. She wrote

'Some ha'e sought it,
Some ha'e bought it,
You ha'e wrought it.'

Concerning his knighthood, which was conferred on him by Queen Victoria during his tenure of the Presidency of the Royal Society of Physicians and Surgeons, he was from home when the *Gazette* appeared. He was quite unaware of its coming, and he told me that his first intimation of it was a telegram of congratulation from one of his friends in Glasgow being handed to him in his hotel before breakfast. The telegram was vague, and it was not till he had gone downstairs and seen the newspaper that he knew definitely the cause of congratulation.

It was characteristic of Cameron that, although feeling the burden of years, he did not sink down under it, but kept going in and out, and calling for friends, till this summer, when increasing feebleness caused him gradually to keep to the house. Up till shortly before his death he was keenly interested in hearing of all that was going on, but he was perceptibly weakening, and the end came very quickly. A great gap has been caused, but it is some consolation to his many friends to know that he passed without obvious suffering. Those of us who knew him well and came under his influence feel thankful that we were privileged to have had him so long as an example. He was in truth

'a verray parfit, gentil knyght.'

IMPERIAL CANCER RESEARCH FUND

DR MURRAY'S ANNUAL REPORT

In the annual report of the Imperial Cancer Research Fund for the period 1927-28 the director, Dr J. A. Murray, F.R.S., outlines a number of general features of the cancer problem frequently ignored in the discussion of special investigations. This report, the twenty-sixth of the series, was presented at the general meeting of the Fund, held on Wednesday, November 28th.

Variations in Susceptibility to Cancer

The conclusion that cancer begins as a local disease has determined general recognition of the fact that in its earliest stage the disease is curable. This conclusion, however, has not always held the field, and, as Dr Murray points out, it has been established only through the experimental investigation of cancer in animals. Tumours, experimentally produced, may be removed at an early stage, or after being allowed to grow for a time, or not at all, the former proceeding, it is found, is effective in preventing both local recurrences and the dissemination of cancer throughout the animal's body. Experiments on these lines have brought to light yet another fact of a general nature. Mice differ so much in their response to irritation that while some subjected to tar painting will show signs of cancer in about four months, others, similarly treated under identical conditions, may remain cancer-free for a much longer period, and a small percentage may fail to develop cancer even after being tar painted for a year. But if apparently susceptible mice, from which tar cancers have been surgically removed, are subjected to a second course of tarring, they are found to be distinctly resistant, and it is, in fact, very difficult to obtain the second tar tumour. The same phenomenon was noted in mice from which spontaneous cancers—for example, of the breast—had been surgically removed, their skin was found to be tar-resistant.

The conclusion, Dr Murray suggests, appears to be inevitable that the factors determining differences in susceptibility are not locally restricted in particular tissues, but are of some general constitutional nature. If this theory

is correct some statistical evidence would be expected showing such general factors to be active in determining the incidence of cancer in the different tissues of man. As a small piece of confirmatory evidence Dr Murray cites the rarity with which multiple malignant new growths have been observed. Moreover, a comparison of the incidence of cancer in men and women in special relation to its incidence in organs peculiar to each sex and in organs common to both sexes, shows that in females over 30 per cent. of the incidence of cancer falls on the specific sexual organs, especially the uterus and breast, while in males the incidence on the specific sexual organs is very low. If such incidence were determined entirely by local factors in the different organs and tissues, one would expect a much higher total incidence of cancer in women, then special sexual organs being so liable to develop cancer. Actually the total incidence is the same for both sexes. In all organs common to both sexes, except the gall-bladder and thyroid gland, the incidence of cancer is higher in men than in women. To account for the apparently equal total incidence by the operation of a local factor in each organ one would have to assume first that something in the mode of life in men sets up with greater frequency local conditions leading to cancer in the organs common to the sexes, and that by coincidence this frequency happens to be of the same order, as that of the incidence of cancer in the organs specifically female.

Comparative Mortality Statistics

Cancer statistics of Holland, Switzerland, and Japan are generally comparable with those of England and Wales and lead to similar conclusions. Of particular interest is the fact that though cancer of the breast is twice as frequent in English women as in Dutch women, and is rare in Japanese women, the total cancer mortality in women of these countries is the same. In Japan there is a very high incidence of cancer of the uterus, in Dutch women, though cancer of the uterus is also only half of that in English women, cancer of the digestive tract is far more frequent, the higher incidence in one group of cancers, both in the Japanese women and the Dutch, almost exactly balancing the lower incidence in the other. If the incidence of cancer were determined entirely by local factors this remarkable phenomenon would have to be attributed to coincidence. Italian figures are at some variance with those of other countries, showing not only a lower general cancer mortality, but a much lower incidence of cancer in males than in females. It is suggested in the report that this might be due to racial factors, it may, however, be accounted for by under-diagnosis of cancer in non-accessible sites, which is more likely to occur in men than in women. On the whole, Dr Murray concludes that the incidence of cancer is determined by general factors, local factors determining merely the site at which the cancer develops.

The Filterable Fowl Tumour

Work on the new fowl tumour, discovered by Dr Beggs in the laboratories of the Imperial Cancer Research Fund is being continued. The importance of this tumour, which has been proved to arise from endothelial cells, lies in the specificity of the "agent" or "agents" responsible for its transmission, in that it restricts its activity entirely to endothelial cells. The view that the filterable fowl tumour is not a true malignant neoplasm, but an infective granuloma, cannot therefore be sustained. Dr A. Carrel's experiments, in which he claims to have produced a typical Rous tumour by injecting into a fowl chick embryo, together with some simple chemical substance such as indol, have been repeated by other workers with negative results.

Diet and Cancer

A large-scale repetition of Fujimaki's experiments has failed to verify his conclusion that stomach cancer may be induced in rats kept on a diet free from vitamin A. In such rats hypertrophy and keratinization of the fore-stomach epithelium is frequent, but no actual cancer, in the stomach or elsewhere, has been observed in the laboratories of the Imperial Cancer Research Fund to follow vitamin A starvation. Moreover, the phenomena described

by Fujimaki, are not specific for vitamin A deficiency but have been observed in conditions of B avitaminosis, and even in old stock rats which had always received a diet adequate in vitamins. Dr Murray states categorically that there is no reliable evidence—experimental, statistical or clinical—which would indicate a causal correlation between cancer and the absence or presence in the excess of any particular dietetic constituent.

Evidence of Transmissibility of Cancer

Experiments carried out in the laboratories of the I.M.D. have shown that Professor Heidenhain's belief in the transmissibility of cancer from animals to man derived from work purporting to prove its transmissibility from man to animals, is based on error. Dr Murray emphasizes the fact that Heidenhain's conclusion, if correct, would revolutionize our conception of the nature and treatment of cancer, and, in so far as it meant that any case of cancer in animals or in man might be a source of infection, would spread profound alarm among the public. Dr Cramer, however, has shown that the malignant growths observed by Professor Heidenhain were in reality spontaneous tumours and not the result of infecting the animals with human cancerous material.

The Warburg Phenomenon

Experiments have shown that the Warburg phenomenon that is, high aerobic glycolysis by cancer cells—normal tissues effecting glycolysis if at all, only when oxygen is absent—cannot serve to distinguish cancerous from non-cancerous proliferations, a singular phenomenon has been observed in the study of cellular overgrowths produced by virus infections. These latter are also capable of effecting a partial splitting of carbohydrates under aerobic conditions. An investigation has also been made into the therapeutic possibility, suggested by Warburg, of affecting cancer growth by varying the oxygen pressure in the inspired air. Prolonged exposure of animals with cancer to high pressure of oxygen, within the limits of safety, produced no effect on the tumours, while low oxygen pressures delayed their growth and produced extensive necrosis. Even prolonged exposure, however, could not completely arrest the growth of tumours, and only produced their regression. Dr Murray concludes that there is no evidence that alterations of oxygen pressure, even within the limits of safety, are by themselves of therapeutic value.

VOLUNTARY HOSPITALS IN GREAT BRITAIN

A SURVEY OF 1927

The ninth annual report on voluntary hospitals in Great Britain (excluding London) for the year 1927 has been compiled by Mr R. H. P. Orde, and is published by the recently constituted Central Bureau of Hospital Information. This agency, which has been set up by the Joint Council of the Order of St. John and the British Red Cross Society in conjunction with the British Hospitals Association, has taken over the work of publication from the Joint Council, in addition to other duties in connexion with the accumulation and distribution of information relating to hospital affairs. Its services are placed freely at the disposal of the voluntary hospitals, and also of public authorities.

The report covers institutions containing over 99 per cent of the voluntary hospital accommodation in Great Britain outside the London area, giving detailed surveys of the financial position of 755 hospitals containing 48,212 available beds, the total number of hospitals in Great Britain, outside London, is given as 760 with 48,696 beds, so that only a very small proportion of the available accommodation has not been brought within the scope of the review. Taken in conjunction with the statistical report for 1927 on the finance of London hospitals, issued by King Edward's Hospital Fund, which was noticed in the *Journal* of October 27th (p. 771) the report affords a practically complete account of the position of the voluntary hospitals. A general summary of the finances of the 755 hospitals reviewed shows that in 1927 the amount of income available for maintenance was £7,103,044 while receipts for capital purposes amounted to £1,511,024, giving a total income of

£8,614,068, the expenditure on maintenance was £6,100,442, and on capital account £1,498,012, leaving a surplus of £1,015,614. The number of hospitals with a credit balance on their maintenance account was 562, or 74.44 per cent of the total, and 7 per cent more than in 1926. As compared with this year, income available for maintenance increased in 1927 by £714,025, and expenditure on maintenance increased by £169,023, receipts for capital purposes decreased by £16,776, and capital expenditure by £237,165. The surplus of £1,015,614 compares with £250,220 in 1926, but was lower than that recorded in the three preceding years.

Details regarding the number of patients treated were obtained from 753 hospitals which provided during 1927 for 729,765 new inpatients and 2,907,193 new outpatients, showing increases of 36,599 and 149,783 respectively over the previous year. For purposes of analysis England and Wales and Scotland, are dealt with separately, and hospitals are divided into three main groups—the first containing those with 100 or more beds, the second those having from 30 to 99 beds, and the third those having less than 30 beds—and certain special groups are also differentiated, such as hospitals associated with medical schools, specially large hospitals, and those devoted to particular classes of disease. The tables relating to the volume of work done in the voluntary hospitals show that in England and Wales there has been a remarkable increase in the number of cases dealt with in the out-patient departments of the large hospitals, out of a total increase of 115,555 in this category, these hospitals were responsible for 113,690. The pressure for bed accommodation in this class was also much greater than in the smaller hospitals. This was also true in Scotland, and in that country, further, the proportion of available beds occupied in all classes of hospital was higher than in England and Wales. A striking feature of the figures relating to these countries is the rapid extension of surgical operative work, it is only possible to give an approximate comparison but it appears that from the details available the number of operations per hospital rose from 698 in 1923 to 866 in 1927. In the therapy, electro-therapeutic and massage departments there has also been a substantial expansion. It is satisfactory to learn that all classes of hospital in England and Wales shared in the general prosperity, and that the position of the large hospitals, which formerly were relatively worse off than others, has improved considerably, the ordinary income of this group having risen from £2,957,375 in 1926 to £3,292,298 in 1927. In Scotland, however, there was little change in the financial position, and the figures suggest that while the English hospitals have more than recovered the voluntary support they enjoyed before 1920 the Scottish are still below the 1925 level.

The main sources of income on maintenance account per available bed in 1927 were as follows for the hospitals of the two countries—Voluntary gifts, England £80.75, Scotland £62.97. Receipts for services, rendered, England £29.40, Scotland £16.30. Interest from investments, England £18.89, Scotland £29.75. Extraordinary income, England £18.93, Scotland £27.15. It will be seen that the Scottish hospitals received much less for services rendered, although income from this source is steadily increasing in both countries, while the accumulation of large invested funds is a notable source of strength, particularly in times of depression which has been fostered in the North. The report contains a series of analyses of hospital expenditure which should be exceedingly valuable to all engaged in hospital management.

Sir Arthur Stanley contributes a prefatory note directing attention once more to the difficulties created by the increasing number of road accidents, and this subject is dealt with also in a series of special articles by representatives of the hospitals of insurance and of the motoring public. Mr Orde, in his introduction to the report, states that from replies received to a questionnaire it is estimated that in 1927 approximately 26,000 inpatients and 39,000 outpatients were treated in provincial voluntary hospitals at a cost of about £230,000 towards which approximately only £26,000 was received from or on behalf of the patients. Lieut. Colonel J. T. Woolrich, Perseus gives an account of the development and working of the St. John Ophthalmic Hospital at Jerusalem. Among supplementary matters are a memorandum on the assessment of voluntary hospitals and an analysis of some contributory schemes for paying or private wards.

The report may be obtained from the Central Bureau for Hospital Information, 19, Berkeley Street, W.1, price 1s. 6d. post free.

Universities and Colleges.

UNIVERSITY OF OXFORD

At a congregation held on November 24th the following medical degrees were conferred

D.M.—R J Brocklehurst H F Turner D G T Horn Cross

UNIVERSITY OF CAMBRIDGE

At a congregation held on November 24th the following medical degrees were conferred

M.D.—A D Whitelaw

M.D. B.Clin.—N R Barroett H S Waters P R Duckton

Mr A I R Wollaston, M.A. B.Ch. D.S.C., has been re-elected to a Fellowship at King's College and appointed tutor

Mr T F Cameron, M.A., has been elected Master of Convillio and Cinis College, in succession to the late Sir H A Anderson M.D., F.R.S.

UNIVERSITY OF LONDON

Mr H L Eason has been elected chairman of the Library Committee for 1928-29

The following degrees have been conferred

D.Sc. in Anthropology—Mr F G Parsons J.R.C.S. University Professor of Anatomy for thesis The Physiology of the Intestine

D.Sc. in Physiology—Mrs Norah Liddle for the Is Study of Absorption in the Stomach and Small Intestine

UNIVERSITY OF LIDS

Dr H H Moll has been appointed honorary demonstrator in pharmacology and therapeutics

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated

SURGERY—J Freud W S Ghal W D Chan-Jones H C Johnson

T.H.S. Lyle A Weeks

MEDICINE—J Freud W D Chan-Jones T C Gross M H Rashwan

L. Wasef

FORENSIC MEDICINE—W D Chan-Jones D F Michael

PHARMACY—A Datta J D B Games I C Cross A Liberis T K S

Lyle A Weeks

The diploma of the Society has been granted to Messrs E C

Gross H C Johnson T H S Lyle M H Rashwan, L. Wasef

Medical News.

THE Fellowship of Medicine and Post Graduate Medical Association announces that a lecture will be given on Monday, December 3rd, at 5 p.m., by Dr C A Sutherland at the Medical Society of London, 11, Chandos Street Cavendish Square, W.1, on 'Some cardiac problems in childhood'. A demonstration on cancer will be given on the following Wednesday by Mr Herbert Paterson at the Wellcome Museum of Medical Science 33, Gordon Street, W.C.1, at 4 p.m., and on the same day at 2.30 p.m., a clinical demonstration in urology will be given by Messrs Atwater Coyte Loughman and Lory at All Saints Hospital on Thursday December 6th, at 10 a.m., Dr Robert Hutchison will give a clinical demonstration at the Hospital for Sick Children. Two lectures and demonstrations are free to members of the medical profession. From December 3rd to December 16th there will be a special afternoon course at the Infants Hospital, under the direction of Dr Eric Pritchard with visits to other centres. This course is of special value to medical officers of welfare centres—the fee is £3 3s. A special course in dermatology at the Hospital for Diseases of the Skin, Blackfriars will also begin on December 3rd, ending on December 14th, and consisting of clinical instruction in the outpatient department each afternoon from 2.30 p.m., with two special demonstrations. The complete list of special courses for 1929 is now available, and may be obtained, together with particulars of the general course of instruction which is continuous throughout the year, from the Secretary of the Fellowship 1 Wimpole Street, W.1. The Fellowship will resume its lectures at the Medical Society of London about the middle of January with a series entitled 'Pitfalls in medicine and surgery'. It is also proposed to hold a further series of demonstrations at the Wellcome Museum of Medical Science, and weekly clinical demonstrations in medicine and surgery will be given at various hospitals.

A LECTURE on life in the Island of Tristan da Cunha will be given in the cinema theatre of the Empire Marketing Board in the Imperial Institute, South Kensington, at 5 p.m., on Thursday, December 6th by Mrs Rose A Rogers, author of *The Lonely Island*. The lecture will be illustrated by lantern slides and films, including that taken of life on the island in connexion with the *Quest* expedition.

A NEW children's wing at the Wembley Hospital was opened on November 21st by Princess Arthur of Connaught. The wing includes a medical ward and a surgical ward (each of eight cots), two observation wards, two private wards, a casualty theatre, and other accommodation. New quarters for the domestic staff have also been provided. The cost of the extension has exceeded £17,000 and only about half this sum has been received. It is hoped that a new x-ray and developing room and a laboratory will shortly be added.

MESSRS EDWARD ARNOLD AND CO announce for early publication a new edition of Garrod, Batton, and Thursfield's *Diseases of Children*, which has been revised throughout and largely rewritten, under the editorship of Dr Hugh Thursfield and Dr Donald Paterson.

THE annual report of Livingstone College for 1927-28 contains an account of the annual meeting in the summer, to which we referred on June 23rd (p. 1096). Sixty-three students entered for various courses held during the year, of whom six took the full course. In addition to these, twenty-seven students attended a short course on the care of health in the tropics. It is stated that the deficit on the year's working is about £50, and an appeal is made for more substantial assistance. The report includes extracts from letters from past students in different parts of the world, emphasising the value to missionaries of the elementary training in first aid and medical subjects which the College exists to provide.

THE following appointments have recently been made in foreign faculties of medicine. Professor Herzog of Innsbruck has succeeded Professor Marx in the chair of laryngology at Munich, Professor Pöckl of Pragno has succeeded Professor Wagner Jauregg as head of the psychiatric clinic at Vienna, Professor Werner Gerlach, professor at the General Hospital at Barmbeck, has succeeded Professor R. Beneke in the chair of general pathology and morbid anatomy at Hamburg. Professor Kurt Brand of Glessen has succeeded the late Professor Johannes Gadamer in the chair of pharmaceutical chemistry at Marburg, and Professor Guiber has been succeeded in the chair of pathological anatomy at Innsbruck by his assistant, Dr. Franz Josef Lang.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are *MUSEUM* 9861, 9862, 9863, and 9864 (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are **EDITOR of the British Medical Journal, Astology Westcott, London**

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements, etc.) *Articulate Westcott London*

MEDICAL SECRETARY *Mediscera Westcott London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Bacillus, Dublin* telephone 62550 Dublin) and of the Scottish Office 7 Drumshigh Gardens, Edinburgh (telegrams *Associate, Edinburgh* telephone 24361 Edinburgh).

QUERIES AND ANSWERS.

A PAGE TURNING DEVICE

"W. N." writes: Do any of your readers know of a mechanical device for turning the leaves of a book? I am writing on behalf of a friend who is paralysed in both upper and lower limbs so that the only motive power could come from depression of the chin. I should be grateful for any suggestions.

INCOME TAX

Allowable Expenses

"R. H." inquires whether there is available for reference a detailed list of allowable expenses as officially approved.

* * * We are not aware of any detailed list to which official agreement has been given, and the circumstances of different cases vary between such wide limits that a list sufficiently

detailed to be really useful is not likely to become available. On the particular class of expense to which "R. II" refers—cost of motorcar, coat and gloves, dust coat etc.—we fear the law is against him: such expenses cannot be correctly said to be incurred wholly and exclusively for professional purposes—they are too personal in character.

Cost of Indoor Assistant

"A. W." inquires what is the usual amount allowed off income tax for food board and lodging of an indoor assistant. He suggests 30s per week, but the Inspector at taxes considers 20s adequate in view of the fact that one third of rent rates etc., have been allowed.

It is impossible to lay down any general rule where so much depends on the circumstances of each individual case. If the one third allowed is adequate to cover that portion of the house which is occupied, wholly or partly by the assistant, and also the relative cost of cleaning, laundry, general domestic service etc., then the question is reduced to an estimate of the out of pocket expenditure on the assistant's food etc. Prima facie the one third is quite as open to attack as the 20s per week.

Expenses of Employment

"A. F. I." inquires with regard to expenses incurred as an assistant medical officer of health.

It is a fact that no deduction can be made in respect of interest which would have been received if he had not had to use the capital to build a garage. On the other hand, deduction can be made in respect of the rental value as assessed to income tax, of the garage so erected. Further the expenses allowable are those actually laid out for the purposes of the employment, and exclude any allowance for work done—for example cleaning, etc. by him self. The authorities are within their rights in restricting the expenses allowed to exclude those which reasonably relate to private use.

LETTERS, NOTES, ETC.

SECURITY OF TENURE IN PUBLIC POSTS

"A. M." writes I watch with interest the discussion initiated by Dr. Molinarius under the title 'Security of tenure in public posts, settling for as it does the many grievances of medical officers in the mental hospitals service, and my only fear is that the dread "this or response must now cease" may appear before the British Medical Association has been induced to do a little more in our behalf. The varied opinions already expressed only go to show the extremes of conditions that exist in different institutions and the need for some uniformity to be brought about by an authoritative body. In my few years of service I have met several colleagues from other institutions all with similar complaints and there has been some talk of forming a society to further our interests without victimization but a higher body such as the British Medical Association is needed for a task of this sort. The main points have already been stressed: security of tenure, participation in administration access to the committee for fair promotion and facilities for study, but, as may be seen from other letters conditions vary from place to place. This is surely an urgent reason for advising against entering the service—the uncertainty of local conditions. Until the British Medical Association can see its way to agitate for justice and equality of conditions the mental service must perforce remain the purgatory of those with influence."

BIOCHEMICAL INVESTIGATIONS IN ALLERGIC CONDITIONS

DR. R. CHALMERS (Darlington) writes: I am in full agreement with Drs. Barber and Orle (November 17th p. 880) when they say that allergy is beyond question the most important biological and medical problem that exists or ever has existed. I have been doing routine chemical and microscopical examinations of urines in my cases for the past ten years, and some five years ago a letter of mine appeared in the *Journal* on what I termed leucina bodies in the urine. I referred to them as being impure forms and the only reason for calling them such was because of their microscopical appearance simulating those depicted in Simon's *Clinical Diagnosis* and that I always found them in cases where I suspected there was present a chemical disturbance of the liver. In the intervening years I have sought in vain to find an explanation of those bodies by sending them to laboratories and to high authorities in the medical world, at last I sent drawings and descriptions of these to the medical journals for publication to try and get some enlightenment. These were returned to me until I could tell what their nature was. I have however kept on noting and recording these and allied findings in my patients and now have records of many hundreds of different kinds of cases. After reading Dr. Orle's account of his ether reaction I had an opportunity of trying it in a case of severe jaundice. I found it strongly positive and on examination of the serum found minute oil globules as he describes and also beautiful specimens of what I have designated leucina bodies. These did not show in the centrifuged specimen of the urine itself. I am very pleased to see that Dr. Orle who found his ether reaction positive first in a case of cardiac failure has raised the point of what relation

this hepatic tendency may have on cardiac pathology. In a paper which I sent to the *Journal* a month ago but which has not been published I refer to the same point and state that it is my belief, come to from continuous observation of my cases along those biochemical lines that the hepatic chemistry is a very important element in such diseases as coronary disease, angina pectoris, and myocardial disease.

PREMATURE SEPARATION OF PLACENTA DUE TO RELATIVE SHORTNESS OF THE UMBILICAL CORD

DR. C. J. HILL (Atherton, Minster near Rotherham) refers to a previous account by him of a relatively short umbilical cord causing retention of the membranes. *British Medical Journal* April 16th 1927 p. 750. He now reports another case of the same kind, in which shortness of the cord caused delay in a breech case until birth of the shoulders the placenta and membranes being torn from their site with subsequent haemorrhage into the uterus. The patient's pulse, which had been normal increased to 120 and she began to look pinched. She was lightly anaesthetized and a boy 5½ lb. was felt rising to above the umbilicus. Despite good pains there was no progress. In the birth of the head owing to distension of the uterus the third stage of delivery was uneventful. Pressure on the abdomen was applied during delivery.

SANITARY INSPECTORS

MR. WILLIAM G. KIRSHAW, J.B.E. (President of the London Centre of the Sanitary Inspectors' Association) writes: I have read with considerable interest the remarks on the teaching of hygiene in your issue of October 27th. I hesitate to question any conclusions at which so great an authority as Professor Jameson has arrived but I would point out that his observations in regard to the general educational qualifications for entrants to the Inspectorate do a great injustice to those who would be candidates who have served the necessary apprenticeship in one or other of the building trades because he infers that apprentices in the building crafts to-day are so lacking in general education as to be unable to pass. If they have not already done so one of the examinations mentioned in the regulations of the Joint Examination Board. If such is the case then I doubt if they would be competent to meet a builder upon his own ground because to-day, clerks of works, builders, and their managers and foremen are generally speaking highly educated men who have found it much more profitable to remain in the building trades where higher remuneration is obtainable than that which the Ministry of Health permits local authorities to pay to their sanitary inspectors. I wholeheartedly admit the great advantage which a practical training in the building trades is to a sanitary inspector and what a valuable asset it is to the authority he serves but if craftsmen are to be encouraged to devote the time and money necessary to obtain the training and qualification in the many duties which a sanitary inspector to-day has to perform which have no association at all with the building trade for example as Professor Jameson points out—a certificate as inspector in meat and other foods then they must be assured that the salaries which they will receive as sanitary inspectors shall be at least as good as those which they may reasonably expect to obtain if they remain in the building craft. The remedy lies in this direction rather than in lowering the educational standard.

OUR LEARNED BROTHERS

"N3" writes Dr. Herbert Spencer's story (November 17th p. 915) of the American obstetrician who derived Caesarean section from *recoedere* reminds me of the surplus I felt when "tactons eruditus" met my eye in (I think) the advertisement pages of a small medical periodical from across the Atlantic.

'HISTORY OF SCARLET FEVER.'

DR. GORONWY JONES (Swansea) writes: In this article (November 24th p. 925) I should like to point out one little error—that is, the date of the quotation from *Pepys' Diary*. In my copy of the *Journal* it is difficult to say whether it is 1654 or 1664. However the correct date is November 10th 1663.

AN ENGAGEMENT CALENDAR

The Diary of Appointments for 1929 published by the Dental Manufacturing Company Ltd (1 Newman Street, W.1) is conveniently arranged and well produced. The pages are spaced for weekday engagements at quarter hourly intervals from 9 a.m. to 9 p.m. and an address book is tucked into the end cover. Many medical practitioners especially consultants should find it just as useful as the dental surgeons for whom it is primarily intended. It can be had in various coloured bindings and interleaved with blotting or ruled paper at the price of 6s. 6d. or 8s. postage 6d. extra.

DISCLAIMER

DR. STELLA CHURCHILL writes disclaiming responsibility for the use of her name in connexion with an advertisement of a brand of India rubber hot-water bottle.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 74, 75, 76, 77, 80, and 81 of our advertisement columns and advertisements as to partnerships, assistantships, and locumtenencies at pages 78 and 79.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 243.

The Lloyd Roberts Lecture

ON

SOME PROBLEMS IN GASTRIC SURGERY

DELIVERED IN MANCHESTER, OCTOBER 23RD, 1928,

BY

SIR BERKLEY MOYNIHAN, Bt, M.S.,

PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

THIS present year has seen a great revival of interest in the subject of gastric and duodenal ulceration. Methods of medical treatment neither new in manner nor now in kind have received a new impulse under new names from those who

"labouring for invention bear arms
The second burthen of a former child"

Bold adventures in surgical procedure have received fresh, unexpected, and even stronger advocacy and support. Experience, it is said, is the name we give to our mistakes, and it is in the hope that my experience of the last thirty years may do something to check newcomers in the field from repeating the errors of their predecessors that I am confirmed in my choice of the subject of this address to-day.

The year began with a paper by MacLean, Jones, and Fildes upon the "Cure of gastric and duodenal ulcers by intensive alkaline treatment." The page heading of this article and in the subsequent lively correspondence is "gastro-duodenal ulcers." There are gastric ulcers and there are duodenal ulcers. The differences between them are not merely geographical. I recall the time when our French colleagues, among others, were profoundly sceptical as to the frequency of duodenal ulcer, and under my own eyes were certainly confusing these two conditions in the operation theatre no less than at the bedside. When that useful landmark the pyloric vein was described, and its value attested by Latarjet and many others, a term of compromise and confusion, "juxtapyloric," was introduced. The use of this term deprives much recent literature, including a laborious investigation by Dr Lucy Wills,² of some of its value, for it is clearly not recognized that pyloric ulcer exists in only one case in a hundred, and that gastric ulcer close to the pylorus is very unusual. In my series of over two thousand cases, less than 3 per cent of chronic gastric ulcers were at the pylorus or within an inch and a half of it.

In my opinion no real advance in our knowledge of the etiology, clinical manifestations, or treatment of these two diseases, gastric ulcer and duodenal ulcer, will be made if we speak of them as one. The time may come when, more fully equipped with knowledge, we may speak of them in synthesis, but for the moment the closest analysis of every particular attribute surely continues to be necessary. These two forms of ulcer occur, as a rule, as Hurst has emphasized, in opposed types of individual. There are, so far as we can judge, some similar factors and some dissimilar factors at work in their production, the chemical condition of the stomach contents in the two conditions is almost always very different, their symptoms enable a clinical and anatomical discrimination to be very frequently, though not invariably, made, their behaviour in respect of haemorrhage and of perforation is not the same, the pylorus forms between them a barrier very rarely overstepped, and finally, a gastric ulcer becomes malignant in a formidable proportion of cases, whereas malignancy in a duodenal ulcer is an event so rare that few pathologists have seen it. The use of such terms as "gastro-duodenal ulceration" and "juxtapyloric ulcer" is, therefore, slipshod and misleading, an evidence of intellectual untidiness, and should be dropped.

It is true that both gastric and duodenal ulcers may be acute or chronic, that when acute they cause a sudden haemorrhage and, very rarely, suffer perforation. Acute

ulcers, as Bolton³ and M. J. Stewart⁴ have shown, are multiple, heal quickly, and often leave little or no trace behind, yet one patch of acute ulceration may persist and lead to the development of a chronic ulcer. Haemorrhage and perforation, though themselves acute, are, with few exceptions, the evidence not of acute but of chronic ulceration which has assumed fresh activity. In a series of gastric ulcers observed by Professor Stewart and myself over a period of twelve years, we found that in 61 cases where death occurred from perforation the ulcer was of the chronic type in 60, in 14 cases whose death occurred from haemorrhage the ulcer was of the chronic type in 13. In the acute case the ulcer was a terminal condition associated with advanced disease, and haemorrhage was not the determining cause of death. In a similar series of cases of duodenal ulcer during the same period this truth also holds good, twelve deaths from haemorrhage all occurred in cases of chronic ulcer, in 17 deaths from perforation there were 109 cases in which the chronic ulcer had given way, in 12 cases acute ulcer was present, so that there were 4 cases in which both acute and chronic ulcers were found—in every one it was the chronic ulcer which had perforated.

I have fully discussed the relative values of medical and surgical treatment in my little work [*Two Lectures*, Wright and Co.], but certain points require, perhaps, a further statement. It is, in the first place, indubitable that both gastric and duodenal ulcers heal, and remain healed. In their sound healing they may produce conditions requiring relief by surgery. "Pyloric stenosis" is virtually always duodenal stenosis, contractures in the stomach are usually in the body of the organ and cause the condition known as "hour-glass." Professor Stewart finds evidence of open or healed ulcers in about 5 per cent of the bodies examined on the *post-mortem* tables in Leeds. Often no history of any period in which symptoms were present is found in the clinical notes, or is to be obtained from relatives. The fact that healing does occur affords, however, a strong, indeed an undeniable, plea in favour of an adequate trial of medical treatment. No surgeon upon whose judgement I would rely suggests operative measures for anything but the rebellious cases or those in which the ulcer is large and incoercible, emergencies, of course, excepted.

In the next place, we must be convinced that an ulcer is in truth present before embarking upon treatment, or building up statistics, and disseminating views based thereupon, as to the efficacy of any specific therapeutic method. Much of the literature on this subject of medical treatment is encumbered with error and with half-truths. In discussing the matter with the protagonists of anonymous methods in other countries I have been distressed to find how slender may be the accepted evidence as to the existence of an ulcer. Unless we know that an ulcer is indubitably present how can we assess the value of treatment which has been supposed to "cure" it? Even radiological evidence must sometimes be criticized. Let me quote Case I from MacLean's paper:

"A married woman aged 30, was admitted on Oct 28th, 1927, and discharged on Nov 19th. She gave a history of very severe upper abdominal pain radiating through to the back. This pain had been present off and on for over three years. In 1925 she was under treatment for some months and again in 1926 for six weeks. During the present year she had never been free from pain and discomfort of some kind. On examination she was well nourished showing very acute tenderness over the right epigastric region otherwise nothing gross was detected. From the time she was put on alkalis and diet the pain disappeared and she made an untroubled recovery. Whereas on Oct 28th she had a very large penetrating ulcer of lesser curvature on Nov 17th the report was no ulcer seen and no tenderness. The patient is now in good health and there are no symptoms of dyspepsia. The epigastric tenderness has also disappeared entirely."

Here is a patient "well nourished," and therefore requiring care in investigation, examined on the day of admission to hospital, when a "very large" ulcer is found. I confess that I should be loath to accept such evidence. What time was given for the due and most needful preparation of the stomach? Does anyone with any experience or of good judgement suppose that a "very large penetrating" ulcer, such as is supposed to be shown in the figure, can disappear in three weeks? Sometimes I am confronted

with a "very large" gastric ulcer too high in the stomach to be resected, in such cases I perform jejunostomy, with or without cholecyst-gastrostomy, or gastro-entrostomy combined with jejunostomy. The healing of the ulcer is watched under x-ray examinations. I have never seen an ulcer of the size depicted in this instance heal completely in less than four months, even when the stomach was in a condition most favorable for healing, being at rest, receiving often the four carbonates or bismuth carbonate alone, all sources of infection having been removed, rest for some weeks being enforced, and all ancillary methods, including blood transfusion, used to advance and encourage healing. It is not enough to see "a disappearance of the crater" of an ulcer to conclude that the ulcer is healed. In the process of healing the first stage is the "flattening out" of the crater, a deep crater becomes shallow, this does not mean that the ulcer is healed, only that the first stage is accomplished.

We must therefore make certain that, in all cases used to establish principles and to inculcate the value of methods, an ulcer is in truth present, that we are walking by sight and not by faith alone. The words "uninterrupted recovery" used in the above report within three months of the beginning of treatment betray an optimism which must excite our envy, but never, I hope, our emulation.

It is not the physician alone who accepts a diagnosis of gastric or duodenal ulcer upon wholly insufficient evidence. As I shall presently mention, the surgeon, whose error is far more serious, may carry out a short-circuiting procedure in cases (unfortunately in many cases) where no trace of an ulcer exists, where indeed other pathological states are present, have caused a number of the symptoms of ulcer, and are completely overlooked. The high repute of medical treatment, no less than the strictures passed upon surgical treatment, are earned in no small degree by a process of make-believe. By drugs and diet no harm is done to an ulcer which exists only in the mind of the healer. Grievous and irreparable harm may be done by the act of the surgeon, and his art brought thereby into disrepute. It is not only the patient who is sacrificed, our cause is wounded in the house of our friends.

Furthermore we must remember that medical treatment is a dangerous, a prolonged, and, I fear, a very tedious business. Our object is not temporarily to abolish symptoms, but to secure the firm healing of the ulcer. To banish symptoms is so very easy, as I have over and over again asserted. To suppose that this implies an "uninterrupted recovery" is to deceive ourselves, and to accept false values.

"One most important point," writes MacLean, "is to warn the patient that if any symptoms return he must go back to milk or light diet for a day or two and take the powder four or five times a day." If symptoms return, what has happened? The unhealed ulcer has probably taken on a new activity, the edge is spreading, there is infection all around, and a local spasm is excited, and if x-rays do not always show this, operation most certainly does. Is the suggestion of a "day or two" of dietary restriction really the best that can be offered? The word "cure" is used almost frivolously by MacLean, for in his paper published in January, 1928, the dates on which treatment began in the cases recorded are November 1926, April 1927, July 1927, April 1927, February 1927, 1927 (no month), July 1927, April 1927, October and November 1927, February 1927, April 1927. Is there anyone who is so beguiled as to feel satisfied that in such cases ulcers are healed and are to remain healed? No account is taken of the seasonal variations, the cyclical character in the symptoms, to which I called attention a quarter of a century ago, nor of the difference between "relief" and "cure." We are, moreover, in ignorance of the frequency of these supposititious "cures" (or of their duration) to the total number of cases treated.

It may be urged that in many cases of gastric ulcer the treatment by intensive administration of alkalis, with the purpose of neutralizing excessive or normal acid, is theoretically unsound. If there is hyperchlorhydria, as in most cases of duodenal ulcer, their value may be understood. But when the acid content is low or absent, what reasons

are there for such large and repeated doses of alkali? I expect we are not so much concerned—at least I am sure that patients are not—with reasons as with results. I am by no means confident, as many are, that good results must be attributed to the neutralizing power of alkalis, but I am content to use these until some wiser investigator discovers the clue, if other clue there be, to their power. Kinsella¹ suggests that the potent effect of alkalis is not so much to neutralize acid as to dilate the pylorus, spasm being overcome, the stomach empties and that degree of rest is allowed which encourages the ulcer to heal.

Because of my leaning to medicine rather than to surgery, I have referred as many early cases as possible of gastric or duodenal ulceration to my medical colleagues for treatment. I may therefore speak with experience of the procedure. All due care must be taken to remove the sources of infection—in the mouth, accessory sinuses, tonsils, and so forth. The commonest origin of infection, the appendix, is inaccessible apart from surgery, for drugs here are useless. Not the least of the advantages of surgical treatment, as I have formerly pointed out, is that it enables this source, and other associated lesions in the gall-bladder, or elsewhere, to be eradicated.

At the beginning of medical treatment rest for a few weeks is absolutely essential. Food in the meagre quantities and at the frequent times laid down as essential by Sippy, Spriggs, Hurst, and Izod Bennett is given, and the triple or quadruple carbonates administered when the acid content is normal or high. Medical treatment should be a matter of as great devotion and surrender on the part of the patient as is surgical treatment. The perfunctory and haphazard procedures which leave too much, leave in fact almost everything, to the patient are the cause of disappointment, and of the "recurrences" or real disasters with which the surgeon has reluctantly and so frequently to deal. The healing of an ulcer is, as a rule with negligible exceptions, a difficult and tedious business, it does perhaps sometimes occur easily, and possibly in recent acute cases even quickly, as *post-mortem* experience suggests, but if we wish to make sure of it, no pains can be too great, for if failure occurs in the first instance it is hardly likely to be so easily accomplished at a second or later trial. My advice to patients is to exercise the greatest possible loyalty to advice in the matter of diet, alcohol, drugs, rest, warmth, and clothing for at least a year and to avoid foolish risks for ever. My very wise friend Dr. Hurst is far too optimistic when he says that "very large chronic ulcers which have penetrated the pancreas or the liver may require as long as three months" to heal. I have known them take over three years. After all it can be no advantage to a callous ulcer, in respect of its power of healing, that it should lie in the stomach rather than elsewhere, let us say upon the surface of a limb. And we do not even there expect to find such rapid cicatrization as MacLean and others suppose.

The patient who has experienced many recurrences, in whom one or more chronic ulcers have existed or are still present, is only wasting time and risking his life, by continuing medical treatment. Though almost all the patients who come to the surgeon for help either in their acute emergencies, or because of protracted disability, have undergone medical treatment on many occasions, it is rare indeed to hear of one who has unfalteringly submitted to the full prolonged ritual. So far as the poorer people are concerned the hospitals of the country are powerless to deal with them, accommodation is quite inadequate. We are driven to cope with catastrophes, but do little to prevent their recurrence. The treatment of gastric and duodenal ulcers in the mass is now an economic rather than a medical problem.

Medical treatment in the past has failed very badly. It fails far too often to-day. Certainly almost all the fatalities in these diseases occur in those who have been submitted to medical treatment, and must accordingly be attributed to the failure of that treatment. This form of treatment, beyond all reckoning more dangerous than surgical treatment, will be even less successful if a free and easy method, acclaimed as adequate by high authority, should ever become popular. If surgery is to meet a smaller demand it will only be when general practitioners

and physicians realize that medical treatment, at present so very unsatisfactory, can only become safe when it is made more rigorous and when loyalty thereto is continued for longer periods. The ambulatory and perfunctory treatment of gastric and duodenal ulcers by triple carbonates, and an inadequate dietary restriction, has added much to my surgical anxieties in the past few months, and I am by no means alone in this unhappy experience.

It is personally interesting to me to recall that on the last occasion on which I referred to the "triple carbonates" I repeated a suggestion I had often made before. It has since been widely noted upon abroad, and at home chiefly by my colleague Mr L R Brathwaite. It was this, that if the success of gastro-enterostomy is to be ascribed to the alkalinizing properties of the bile which enters the stomach through the new opening (if, that is to say, my friend Mr H J Paterson is right in believing the operation to have a "physiological" action), it would surely be better to anastomose the gall bladder to the stomach, so that the supply of alkali should be continuous and automatic. I have performed this operation in cases of inaccessible large ulcer in the stomach with a normal or high acidity and in cases of jejunal ulcer it is too early yet to speak of permanence in the good results. For details of this method I may refer to the paper of Mr Brathwaite.

In spite of the most careful and protracted medical treatment a certain proportion of cases of gastric and of duodenal ulcer is found irremediable except by surgery. The proportion will vary according to a number of factors: the age and general condition of the patient, the duration of the ulcer, the care exercised over intensive medical treatment and its duration, the subsequent attention paid to diet and other matters, the occurrence of haemorrhage, of stenosis, or of chronic perforation with adhesion to neighbouring parts and in the case of the stomach the tendency to carcinoma. All ulcers, or almost all, should at first be so diligently treated as to encourage healing, but not all ulcers are capable of healing. I have no means of knowing the number of recalcitrant cases and all estimates are open to objection. Donald Balfour⁸ asserts that in the aggregate these complications occur in 67.3 per cent of cases of gastric ulcer. In the Mayo Clinic however as in all large hospitals, it is chiefly the rebellious cases which seek relief, the earlier cases are dealt with nearer home and if treatment proves successful do not reach the consultant or the hospital. Forman⁹ in a small number of cases carefully followed and examined found 57 per cent of failures after medical treatment. David Smith¹⁰ gives the results of medical treatment in 214 cases observed between 1913 and 1922. If immediate results are accepted it is found that 67 per cent of males are "cured," and 2 per cent die of females 76 per cent are "cured" and 5 per cent die. Of cases observed between five and fifteen years after treatment 29 per cent of males were cured and 19 per cent died, of females 40 per cent were cured and 15 per cent died.

So far as duodenal ulcer is concerned I think it is very rare for any patient who has given a quite definite history of two or more attacks to recover permanently and completely. Subsidence of symptoms and freedom from recurrence for months, or even for years, may often be observed as I pointed out long ago but in the end there is a fresh outbreak of trouble.

This recrudescence of symptoms is due to various causes. An indolent unhealed ulcer clinically unobtrusive in its callous state may have assumed a new activity of destruction at some part of its edge, or an old ulcer lightly healed may have broken down afresh or an infection in the mucosa near the chronic ulcer may have led to the appearance of an acute ulcer or, rarely, an entirely new chronic ulcer may be developing. We cannot always decide which of these events has happened but we may safely say that as a rule it is an incompletely healed callous ulcer which breaks down. I have seen this repeated recrudescence in literally hundreds of cases indeed a very large proportion of patients upon whom eventually I am compelled to operate give a history of repeated attacks followed by intervals of repose. The permanent "cure"

of the patients after the most praiseworthy devotion to treatment is indeed a rare event when the ulcer is in the duodenum and has suffered relapse.

The main indications for surgical treatment in cases of duodenal ulcer are recurrence of symptoms, stenosis and haemorrhage. During the last few years surgeons in some parts of the world have been in revolt against short-cutting operations. My friend Professor Pannett¹¹ in this country is, to my regret and surprise, among the irreconcilables. My own opinion of these operations (gastro-enterostomy and gastro-duodenostomy), based upon a longer experience than that of any surgeon now in active practice in this country (for I was the first surgeon to operate upon a duodenal ulcer which had been previously diagnosed), is that they have very strong claims to be considered as among the most successful of all abdominal operations. Wherein lies the cause of so grave discrepancies in opinion?

In the treatment of a duodenal ulcer by operation gastro-enterostomy alone should never be performed. In all cases the ulcer must be dealt with directly by one device or another. Over twenty years ago I learnt this lesson for I found, after "successful" gastro-enterostomy, that one patient died three years later from perforation of the original untreated ulcer, and that one patient (whose second operation was witnessed by Dr J B Murphy) had a recurrence of symptoms, with haemorrhage, and the original ulcer, or no ulcer in the same position was found in a state of great activity. I have operated for haemorrhage in several cases where other surgeons have performed gastro-enterostomy, and have found the original ulcer untouched at the first operation, in an acutely active condition with large vessels entering it. I have therefore urged that in all cases of duodenal ulcer the ulcer itself must be treated directly, whether gastro-enterostomy or gastro-duodenostomy is performed, the appendix must then be removed and the gall-bladder, spleen, and liver examined. Treatment of the anterior ulcers is not difficult. If the ulcer is on the posterior surface, with or without an anterior ulcer, the duodenum may be opened, the ulcer cauterized, and the pylorus temporarily closed by an encircling suture.¹² It is possible that on *post-mortem* examination a lesion of the posterior wall may be found more often than my operation figures indicate. The fact remains that in the cases requiring surgical treatment the anterior ulcer is more often present, and that when two are present the anterior is the older. The exceptions to this are less than 20 per cent in number.

The necessity for direct treatment of the ulcer is not recognized even by the latest writer,¹³ and no doubt his dissatisfaction with the operation of gastro-enterostomy is based, in part at least, upon the inadequacy of his attack, if indeed there has been any, upon the ulcer itself. But both before and after operation something more requires to be done. The patient must be carefully prepared, and regard must afterwards be paid both to diet and to drugs. Cure must be exercised for months. The healing of the edge of an anastomosis does not occur by first intention. Until healing is complete bismuth carbonate or the "triple carbonates" should be given, and a special diet advised. In competent hands, and with the care before and after operation that are required, the mortality is now not more than 1 per cent. Pannett¹⁴ assesses the mortality at 4 to 5 per cent, and adds that it is bound to be higher in the statistics of those surgeons who reserve it for the worse risks. Dr I Bennett¹⁵ in referring to my work spoke of my "selection of cases." The suggestions here implied are that the mortality is low because of a choice exercised among the cases submitted to operation: that cases with high risks are omitted, and that in consequence the mortality is small. This is not the true position. I never make any selection of cases, except among early ones which are referred to the physician or to the general practitioner: all cases in need of surgery receive it. There is however a selection of the day for operation. Patients may be kept waiting for two or three weeks to receive transfusion of blood and other most necessary preparation. The immediate slip-die attack is foolish, a selection of cases for the reason implied

would be criminal. The truth is that patients suffering from chronic duodenal ulcer are "good surgical risks" unless there has been a recent haemorrhage. This is indicated by insurance statistics, which show a prospect of life above the average for those surviving operation.¹⁶

What are the ultimate results of gastro-enterostomy? The differences given by various operators, from parts of the world far apart, are inexplicable. The causes of complaint after gastro-enterostomy should now be due to no technical detail directly concerned with the operation itself, but only to conditions which develop subsequently. Mr. Lalor¹⁷ gives a disturbing account of 36 per cent of "unsatisfactory" cases. A review of my cases shows that indifferent results, which are in the gross about 6 to 8 per cent, include complaints of "indigestion," haemorrhage, "recurrence of symptoms." A review of unsatisfactory cases submitted to me after operation by others shows that the commonest cause of disappointment is the wrongful performance of the operation. In my book on *Abdominal Operations* I have dealt with the conditions for which I have known this operation to be practised. They include lead poisoning, the vomiting of pregnancy, rickets, proptosis, cholelithiasis, tabes dorsalis, achlorhydria, and so on.

The very success of gastro-enterostomy in the appropriate case has led to its unjustifiable performance in the cases not requiring it—in cases where the symptoms mimic those of organic disease of the stomach or duodenum. The operation is blamed, the fault lies wholly with the operators. In such cases the anastomosis must often be undone, and the treatment of the patient begun afresh. If the operation is adequately performed in the case fully requiring it, and if reasonable care is subsequently exercised, two conditions only in my experience cause anxiety—haemorrhage and gastro-jejunal ulcer. Haemorrhage occurs, as a rule, from an ulcer at or near the anastomosis, which may declare itself in no other way. It occurs also in cases where less than adequate attention has been paid to the teeth. Removal of infection from the mouth will sometimes prevent recurrence of haemorrhage, as Kusterman¹⁸ also has shown. Bleeding is found sometimes in those whose blood coagulation time, for some reason, is longer than the normal, and in those whose spleen is enlarged. I have twice operated upon cases of duodenal ulcer in patients suffering from early splenic anaemia. Haemorrhage occurred after the performance of gastro-enterostomy, and the spleen had subsequently to be removed. Haemorrhage may occur from an acute ulcer, not recognizable on the operation table, and with difficulty discovered, or discovered when recently healed, upon the post-mortem table. I think I have rarely if ever read any statement so opposed to my own experience as that of Pannet¹⁹ when he says: "The liability to haemorrhage from a gastric, but particularly a duodenal ulcer, is about as great after an operation as before." The only possible explanation seems to be that gastro-enterostomy is performed in cases of gastric ulcer for which it is unsuitable, and that where an ulcer lies in the duodenum it is left untouched, that, in short, little has been accomplished by the operation either to affect the healing of the ulcer, or to remove it.

The real drawback—indeed, in my experience the only serious one—to the operation of gastro-enterostomy is the occurrence of a gastro-jejunal ulcer. The frequency of this appears to be extremely variable. Mr. Digby Chamberlain searched the records of my cases over a period of twelve years, ending more than two years ago. He found that 184 per cent of cases had developed a secondary ulcer. As a rule this form of ulcer, if it comes at all, comes within two years of the operation, some few cases begin while the patient is still in hospital, no relief whatever following the operation, but I have known cases develop as much as nineteen years later. Let me, therefore, to be safe, assess the frequency of this ulcer in my own series at 4 per cent. In such cases a further operation, detachment of the jejunum, followed sometimes by gastro-duodenostomy, gastrectomy, or jejunostomy with which I am well pleased may be performed. The immediate results of these operations are good, the remote results

leave still much to desire. The ultimate results of the operation of gastro-enterostomy are spoiled by this complication in probably 4 to 5 per cent of cases. Much lower and far higher estimates than this are given. Mr. A. H. Burgess, a most accomplished artist in surgery, has rarely, if indeed ever, observed jejunal ulcer among cases operated upon by himself. The highest is that of Dr. R. Lewisohn,²⁰ who, in a series of 68 cases, found 23 (34 per cent) who had developed gastro-jejunal ulcer. In consequence of this unhappy experience Dr. Lewisohn and many other surgeons follow the lead of Haberer¹ and advocate the routine performance of partial gastrectomy for duodenal ulcer. Before I entertain so repugnant a proposal I should like to feel that gastro-enterostomy is given, what it certainly has not yet received, a fair chance. I suggest the following procedure as an invariable routine:

- 1 A careful examination and preparation of the patient in respect of blood condition, teeth, sinuses, etc. so that the operation may be performed at the time the patient is most adequately prepared to undergo the ordeal.
- 2 Confirmation of the clinical diagnosis: the ulcer being seen, felt, and shown.
- 3 Destruction of the ulcer or ulcers by the cautery or other wise repair of the duodenum followed by a short-circuiting operation, gastro-enterostomy or gastro-duodenostomy, the opening being of large size.
- 4 Removal of the appendix: examination of the liver, gall bladder, spleen and other abdominal organs.
- 5 Care in the diet (a printed diet being given), abstinence from tobacco, alcohol, and salt; the administration of the triple carbonates, regard to rest and warmth for a few months at least.

With these precautions fully observed we shall hear very little either of the mortality or of disappointments after gastro-enterostomy. The advocacy of gastrectomy for duodenal ulcer because of the supposed ill effects of gastro-enterostomy leaves me in consequence quite unmoved. As I have said, the defect in relation to the short-circuiting method lies more often with the operator than with the operation. The recommendation of other and more extensive procedures lacks, therefore, in my most deliberate judgement, any initial justification. What, then, is to be said in regard to gastrectomy when performed for duodenal ulcer? There is no doubt that, even in the most skilful hands, it is a more serious operation. The cases which are supposed more especially to require it are those with deep excavating ulcers on the posterior surface of the duodenum. In these cases, and to a certain degree in many others, the removal of the duodenum may, and indeed does, present difficulties and closure of the stump of the bowel may be so arduous and uncertain a task as to suggest to one if its warm advocates the need for drainage. But what if the duodenum leaks? The mortality in the hands of its supporters is from 5 to 10 per cent. Mr. N. Lake²² gives 9 per cent, Okinczev²³ gives 13.6 per cent. Less practised operators will show an even higher mortality. The unanswerable deduction is, therefore, that if after gastro-enterostomy every case eventually unsatisfactory were to die from the operation, the survivors in whom the result is good would be equal in number to the survivors after gastrectomy. Those who die after gastrectomy, that is to say, are equal in number to those who in my own practice die after gastro-enterostomy plus all those who ultimately prove unfavourable cases. But are the survivors after gastrectomy in any better case than the survivors after gastro-enterostomy? The answer is as yet uncertain, because of the recent date of many operations, and of the absence of any series of cases from competent operators in which a late history is available. The facts that are accessible appear to show that gastrectomy for ulcer in the duodenum has the same defect as gastro-enterostomy—whether in the same proportion or not is unknown. Those who advocate gastrectomy assert that secondary ulcers will be unlikely to follow because of the inactivity which results. But anacidity does not result even when two-thirds of the stomach have gone, and secondary ulcers do undoubtedly follow (Klein).²⁴

Louria,²⁵ reporting some of Haberer's cases, writes: "Studies of the gastric content of the stomach after

gastric resection showed either a total absence of free HCl or greatly reduced figures." Finsterer, realizing that the ordinary method of gastrectomy does not produce acidity, advises that three-fourths of the viscous should be removed. In many of my cases of gastrectomy for gastric ulcer when the acid curve has been normal or high (an unusual condition) test meals taken many months later still show the presence of free HCl. Even when less than one-third of the stomach remains, acid may be produced. I have now had under my own care in a series of just over 100 cases of gastro-jejunal ulcer, 12 cases which followed gastrectomy performed for a secondary ulcer at, or near, the site of a gastro-enterostomy originally undertaken for duodenal ulcer, one case of secondary ulcer after primary gastrectomy for duodenal ulcer, and one case after Devino's operation. Dr Hurst states "that there are in the literature 100 cases of secondary ulcer after gastrectomy. I have never seen such an ulcer when the stomach has been removed for gastric ulcer, but my friend Mr. Fincher records one case." It is clear, therefore, that the chief claim of the advocates of gastrectomy, that secondary ulceration is avoided, cannot be substantiated. There seems to be an inveterate and unconquerable tendency on the part of a few patients to develop ulcer in spite of all our care. These patients are of the "hypersthenic gastric diathesis" described by Hurst.

Haberer's results, both immediate and in the early years after operation (thoro has not yet been time to observe late results), are less satisfactory than many surgeons are able to secure by simpler methods than his. Louria, in reviewing 166 cases of duodenal ulcer operated upon by Haberer between January 1st, 1925, and January 1st, 1927, gives the immediate mortality of gastrectomy as 8.4 per cent. 107 cases were traced, and the results were classified as excellent in 83, "fair" in 16, and "poor" in 6, of whom 2 developed gastro-jejunal ulcers. Having regard to the fact that the first case in the series was operated upon less than four years ago we may assume that this is the best that can be said for gastrectomy. Is this satisfactory? As compared with my own experience it is far less satisfactory than are the results of gastro-enterostomy.

We may then, well ask, What possible grounds for the advocacy of gastrectomy can be established. It is evident that it is dangerous even in the hands of its warmest advocates, a mortality of 5 to 10 per cent. is, in my judgement, prohibitive, for it means that a larger number of people are caused to die in order that a smaller number may live to experience a possibly slighter chance of developing a new ulcer. The clinical results, in my experience, do not in any particular show to advantage when compared with those of gastro-duodenostomy or gastro-enterostomy, and there is certainly not a great degree of freedom from the only serious sequel, gastro-jejunal ulcer. My own unequivocal and most confident opinion is opposed to it. It is one more evidence of the familiar Teutonic capacity for finding a difficult way of doing easy things. I regret that the wise and cautious judgement, the sanity of outlook, and care for the individual patient, which hitherto have always characterized British surgery, have not rendered all our surgeons immune from rash and most intemperate persuasions by Continental and transatlantic operators. In surgery the search is always for safety and simplicity in full accomplishment of our object. Gastrectomy for duodenal ulceration is neither safe nor simple, nor does it bring an adequate reward, if indeed it brings any slightest reward in the form of better ultimate results. We know the worst of gastro-enterostomy, the best is unsurpassable, we have yet to learn the worst of gastrectomy, though what we know is bad enough. The best that I am told of gastrectomy, and the little that I see of its results, leave me in the most contented frame of mind with regard to gastro-enterostomy, provided always that strict observance has been paid to all necessary details concerned with its performance.

In describing short-circuiting operations a Continental surgeon has written a paper upon "gastro-enterostomy, a disease." The title is admirable. Gastro-enterostomy is a disquieting and formidable disease—serious, widespread, and highly contagious—but its victims are to be found

among surgeons rather than among patients. It is the irrelevant application of the operation to unsuitable cases, and its imperfect performance in cases that do require it, that have brought it into disgrace and disrepute. Over twenty years ago I urged that the operation should never be practised unless the ulcer was "visible, palpable, demonstrable." The unwarrantable procedure of "gastro-enterostomy for symptoms" still goes on all over the world, and Dr Hurst is in consequence driven to say that among his private patients "gastro-enterostomy is the commonest gastric disorder of to-day, and undoing gastro-enterostomy is the gastric operation we most frequently recommend." Dr Hurst knows quite well that in making this statement he is offering no contribution to the question of the surgical treatment of gastric or duodenal ulceration. I have "undone" several cases for him, and a large number referred to me by other surgeons. I have never met with a single instance in which, this deplorable procedure being necessary, there was any unequivocal sign of an old or a recent gastric or duodenal ulcer. Where the operation has been necessary the junction need never be separated, except, of course, in cases of jejunal ulcer, when the normal channel is to be restored or gastro-duodenostomy is to be performed. The necessity to undo an anastomosis is not a reflection upon an accredited surgical operation, but upon the judgement of the physician who advised it or of the surgeon who performed it. I mention the physician deliberately. To a few surgeons who have performed a needless operation I have written for details of the conditions found, and have received a reply that the short-circuit was made upon the advice and at the direct request of a physician. During an operation a competent surgeon never needs advice from anyone as to the procedure he should adopt, no physician can possibly understand the surgical indications, the technical procedures, their appropriate application or their probable results as well as the surgeon, upon whom alone responsibility for the technical part of the operation must always rest.

CONCLUSIONS

What, then, are my conclusions in regard to the treatment of gastric and duodenal ulcer?

1. Ulcers of the stomach or duodenum do heal, and remain soundly healed for years.
2. When healed, stenosis in the body of the stomach or in the duodenum may result, and surgical treatment for a mechanical deformity then be necessary.
3. Medical treatment should always be given a first and a second trial, if it then fails success in later efforts is extremely improbable.
4. The present methods of medical treatment are proved by experience to be of little value, and are highly dangerous. The majority of patients who die from either of these diseases succumb because medical treatment has failed to relieve them. Medical treatment undoubtedly has a mortality greatly exceeding the highest mortality following any surgical procedure adopted for chronic ulcers of the stomach or duodenum.
5. The failure of medical treatment is largely due to its insufficiency. To be successful such treatment must be rigorous and protracted. The loyal co-operation of the patient is essential. Very few patients now receive any treatment offering a reasonable prospect of healing of the ulcer.
6. When medical treatment has failed surgical treatment must be adopted and should not be delayed.
7. Experience shows that surgical treatment, adopted when medical treatment has failed, is far less dangerous and far more effective in attaining our object than medical treatment, the immediate and remote mortalities are smaller, the after effects far more satisfactory.
8. The failures of operative treatment by competent surgeons are due chiefly to the development of fresh ulceration at the new anastomosis.
9. The causes of this new ulceration lie partly in the diathesis of the patient and partly with details of the operation.
10. Surgical treatment should consist in the eradication of the ulcer or ulcers, by gastrectomy if the ulcer lies in the

stomach, by a short encircling operation combined with destruction of the ulcer when it lies in the duodenum Balfour's method and Walton's method have proved excellent in the hands of their authors. Other complementary procedures within the abdomen must be observed.

11 Gastrectomy in the treatment of duodenal ulcer is more dangerous than gastro-entrostomy, and does not appear to give any better late results, if indeed its results are so good. It should therefore have no place among surgical methods for the treatment of duodenal ulcer at the present time.

12 The medical treatment of gastric ulcer and of duodenal ulcer is perhaps not so much a medical problem as a problem in social economics. Rest in bed, freedom from anxieties, abstinence from work, complete repose in fact, are essential if treatment is to have the best chance of success. A counsel of almost unattainable perfection!

13 The connexion between gastric cancer and gastric ulcer is so clear³⁰ that gastrectomy alone, wherever it is practicable, should be regarded as the appropriate surgical treatment for chronic incoercible gastric ulcer.

THE INTERPRETATION OF THE RADIOGRAPHIC APPEARANCES OF GASTRIC ULCER

A. E. BARCLAY, OBE, M.A., M.D. CAMB.,
D.M.R.E. (Camb.)

When a radiologist detects a projection on the outline of the opaque food in the stomach he makes a positive diagnosis of an ulcer, and when the apparent pocket is deep he describes it as a "penetrating" ulcer. The question that arises is whether he is or is not justified in making the statement that it is a "penetrating" ulcer. We have all seen "penetrating" ulcers—ulcers that apparently penetrate into the stomach wall, sometimes even showing

hardly penetrated the muscular coat at all, and with no overhanging of the edge. It is difficult to imagine how an ulcer of this type could have given rise to such a definite x-ray picture of a pocket, for in the actual excised specimen there was nothing to suggest the presence of either the niche that held the opaque food in a deep cup or the pocket of air above it. There can be no doubt, therefore, that the conditions seen at x-ray examination must be far different from those that we find either in the excised specimen or even on opening the stomach at the operation when anaesthesia and other abnormal conditions are present.

The only reasonable explanation of such discrepancies is that, in life, the mucous membrane may be heaped up around the ulcer to such an extent that it actually over-

FIG. 1.—Large ulcer on lesser curvature probably penetrating into the muscular coats. Suggested outline of the base of the mucous membrane indicated by a dotted line.

FIG. 2.—Small ulcer on the lesser curvature possibly healing. Suggested outline of the base of the mucous membrane dotted in. Note the half shadow around the base of the ulcer suggesting the thickening of the mucous membrane. (S 190 24)

a small bubble of occluded air above the opaque food in the niche. When such a pocket is fixed on palpation there seems little room to doubt the true nature of the condition. Yet I have seen these radiographic appearances when excision has shown merely a flat ulcer that

laps the ulcerated surface, and thus forms a surrounding crater. On many occasions, by the aid of radioscopic palpation, I have convinced myself of the presence of quite minute ulcers by reason of the residue left in such pockets when the opaque food has been manipulated up

and down the rugae. The smallest of these ulcers that I have seen after excision was not more than an eighth of an inch in diameter, and did not even penetrate the whole thickness of the mucous membrane. The crater in this specimen was far too shallow to account for the definite

appearance of the crater. I have on a number of occasions suggested that the ulcer was healing, and this opinion has been confirmed both clinically and by further x-ray examination.

Radiographically we can diagnose an ulcer, but we cannot

FIG 3.—Ulcer on the lesser curvature. Suggested outline of the base of the mucous membrane dotted in. Note the half shadow below the ulcer due to thickening of the mucous membrane. (S 1070/24)

and quite heavy shadow of the food residue that was constantly retained on palpation. I am quite certain, therefore, that when radiologists detect what we describe as a "penetrating" ulcer they are often picturing a much more extensive pathological condition than actually exists. If I am right in my deduction we may, and actually do, get an appearance of a penetrating ulcer from a mere erosion of the mucous membrane, the heaped-up surrounding mucous membrane being almost entirely responsible for the depth of the crater and for the appearance of "penetration."

If this explanation is correct there is little difficulty in understanding how even apparently large ulcers can disappear in a comparatively short time—a sequence that radiologists frequently have the opportunity of observing. It would be obviously impossible for a real penetrating ulcer of chronic type to heal in so short a space of time as a few weeks, but far from improbable that an erosion should heal in this time. Moreover, the way in which such ulcers close in, radiographically, seems to point to the correctness of this deduction—we do not see the edges healing over the crater and tending to enclose the pocket. As healing takes place the crater becomes shallow and V-shaped and then flattens out—indicating to my mind, that as healing progresses the surrounding mucous membrane loses its heaped-up character and the local contour assumes its normal level. On the V-shaped appear-

FIG 4.—Large ulcer on the lesser curvature. Patient in supine position. The stomach lies over the vertebrae and there is therefore slight pressure on the region of the ulcer. Note the half filling of the shadow around the ulcer due to the extensive thickening of the mucous membrane with the distorted rugae radiating towards the ulcer. Suggested outline of the base of the mucous membrane dotted in. (S 302/24)

as yet be certain whether we are dealing with a perforating ulcer, a penetrating ulcer, or a mere erosion, the apparent depth of the crater probably depends far more on the surrounding thickness and puckering of the mucous membrane than on the extent of the actual damage to the coats of the stomach, the degree of local spasm of the mucous membrane will depend on the irritation from the ulcerated surface. As this ulcerated surface heals and becomes less sensitive, so the local spasm of the musculature in the mucous membrane will subside, with the result that the crater will no longer be of the nature of a pocket, but a V-shaped niche.

In looking through a number of radiographs of gastric ulcer there is a certain amount of evidence that this hypothesis is correct, as will be seen on reference to the radiographs reproduced.

I suggest, therefore, that the nomenclature used by the radiologist is at fault, and that although what he sees may indicate a deep

FIG 5.—a and b Typical x-ray appearances of gastric ulcer on the margin near the lesser curvature. c Crater of ulcer hidden among the folds of the mucous membrane on the anterior or posterior wall. d, e and f Diagrams of pathological specimens of perforating, penetrating, and mucous membrane erosion ulcers. g Suggested interpretation of the x-ray appearance of the pocket being due to overfolding of the heaped up mucous membrane. h Diagram of suggested conditions on healing of ulcer. The mucous membrane loses its heaped up condition the ulcer becomes shallow and conical or V shaped before it disappears.

crater on the outline of the contents of the stomach, yet he is not justified in calling it a "penetrating" ulcer. The radiologist has no means of determining whether this ulcer crater is formed merely by a heaping up of the mucous membrane or whether it is in fact due to a "penetration" of the muscular coat or even to an actual perforation into a dense mass of surrounding reaction.

Professor of Pharmacology and Therapeutics, Queen's University
of Belfast

It is unlikely that chemical analysis of the urine can be of much use in the differential diagnosis of unilateral kidney disorders, because various pathological conditions may produce similar effects on renal function, but analysis of the urine will seldom fail to distinguish the affected from the normal kidney. The urine from the affected kidney is nearly always less concentrated, as Bullerton's¹ specific gravity test usually shows, and chemical methods are more sensitive than the specific gravity test in detecting this change. In considering the results of analysis it must be remembered that urines collected separately from the two kidneys are not always identical in volume or in composition, even when both kidneys are normal.² The differences then, however, seem to be comparatively small, and may be due, for the most part, to irritation produced by the ureteral catheters.

The chief value of chemical analysis lies not in diagnosing the presence of calculus or tubercle, but in the possibility of estimating the degree of injury to the kidney cells.

There is no doubt that a unilateral diuresis of reflex origin can be produced without injury to the kidney. This diuresis is an effect of irritation on the nervous control of the blood supply, and is probably the first result of ureteric calculus and of the toxins of tubercle. The most important problem, from a biochemical aspect, is to distinguish this reflex diuresis from loss of concentrating power due to inefficiency of the kidney epithelium. The volumes of the urines from the two kidneys cannot as a rule be determined with accuracy, since the amount of leakage past the catheters cannot be ascertained. The recognized characteristics of diuresis must be compared with those of renal failure and the results applied to the study of unilateral kidney disorders.

Diuresis

1. In diuresis the urine becomes more like the plasma, perhaps because the kidneys have less time to produce alterations. This generally means that all the constituents of the urine become more dilute. But if the concentration of chloride in the urine before diuresis was lower than that in the plasma, this approach to the plasma involves an increase in the concentration of chloride while the concentrations of other substances are reduced.

In the usual forms of diuresis a rise in chloride concentration can rarely be observed, since the plasma dilution which causes the diuresis also lowers the plasma chloride, and hence tends to lower the chloride of the urine. In unilateral reflex diuresis plasma dilution does not occur, and in any case a comparison is made between urines excreted simultaneously by two kidneys supplied with the same blood, and not between urines excreted in two different periods during which the composition of the plasma has altered. Therefore in suitable conditions, a rise in the concentration of chloride may be expected. To say that during diuresis the urine approaches the plasma in composition is probably less correct than to say that it approaches the glomerular fluid. And if, as is generally supposed, this fluid is a protein-free filtrate from the plasma, we cannot escape the conclusion that a Donnan³ equilibrium exists at the filtering membrane and that the concentration of chloride in the filtrate is higher than in the plasma (cf. cerebrospinal fluid). Wearn and Richards's⁴ analyses of glomerular filtrate furnish direct evidence that it is higher. This point is mentioned in the interests of accuracy, but has not been considered in examining the results. It may render interpretation difficult when the concentration of chloride in the urine happens to be near the plasma concentration, since it may determine the borderline between rise and fall in the urine chloride as an effect of diuresis.

2. In diuresis the various constituents of the urine do not all suffer an equal lowering of concentration. Chloride is less affected than other substances, and urea is probably somewhat less affected than phosphate and creatinine. The following explanation is given by Cushny.⁵

The urine is concentrated by absorption of water from the glomerular filtrate and not by secretion into it of dissolved substances. Chloride is readily absorbed with the water, and although in diuresis the escape of fluid may result in a lower concentration of chloride in the urine, this effect is partly counterbalanced by the fact that less of the chloride itself is absorbed. Urea is normally absorbed to some extent, but much less easily than chloride, while it is doubtful whether creatinine is absorbed at all. Urea thus shares a little of the advantage gained by chloride in diuresis, but always shows a net loss of concentration, and since creatinine, unabsorbed in any case, has nothing to gain by rapid passage through the kidney, its loss of concentration is more extreme. The rejection of this theory will not, of course, affect the validity of the observations.

Renal Failure

In this, as in diuresis, there is a fall in the concentration of the urine, but careful study reveals certain distinguishing features.

1. There is evidence of failure in chloride excretion, and in the later stages the concentration of chloride in the urine remains below that in the plasma even when salt is given to the patient.^{6, 7}

2. There may be defective excretion of urea. This is not easily recognized, except by concentration tests or by examination of the blood, and both of these methods would probably fail in the present investigation. But urea excretion suffers before that of creatinine,⁸ and if the concentrations of these substances can be compared in corresponding samples of normal and abnormal urine any existing defect should become apparent.

The best examples of renal failure are witnessed in chronic interstitial nephritis and in arterio-sclerosis of the kidney. The order in which this failure involves the various constituents of the urine seems related to the degree of resistance which the normal tubule epithelium offers to their passage back from the glomerular filtrate to the blood while absorption of water is proceeding. Thus, chloride passes back most readily, next urea, next phosphate, and creatinine with the greatest difficulty. And in nephritis chloride excretion appears to suffer first, then that of urea, phosphate, and creatinine, in this order. To avoid misunderstanding it should be mentioned that nephrosis or pure hydraemic nephritis is not a good example of renal failure. Function tests give no evidence of failure, and the low water and chloride output in this disease can be attributed for the most part to other causes.⁹ In dealing with unilateral kidney disorders blood area estimation is usually of little value, because one healthy kidney is sufficient to keep the blood urea normal. Concentration tests may have a limited field, but require less direct interpretation than in nephritis, for reflex diuresis, even without renal failure, would probably prevent good concentration of urea.

There remains the application of the above criteria to unilateral disorders, as a method of distinguishing reflex diuresis from renal failure. The urines from the normal and the affected kidney must be compared. The following statements are deduced from the considerations already discussed.

(a) In reflex diuresis the ratio of the chloride concentration in the urine from the affected kidney to the chloride concentration in the urine from the normal kidney should be greater than the corresponding ratios for urea, phosphate, and creatinine. (See Table I.)

TABLE I
Urine in Reflex Diuresis (Movable Kidney)

	Chloride (NaCl)	Urea.	Phosphate (P ₂ O ₅)
	Per cent	Per cent	Per cent
(a) Normal kidney	1.72	1.74	0.094
(b) Affected kidney	1.53	1.39	0.069
Proportion of (b) to (a)	89	80	73

* Note that the concentration of chloride is less reduced than those of urea and phosphate.

Urine from Damaged Kidney (Pyonephrosis)

	Chloride (NaCl)	Urea	Phosphate (P ₂ O ₅)
	Per cent	Per cent	Per cent
(a) Normal kidney	1.45	1.02	0.62
(b) Affected kidney	0.63	0.59	0.039
Proportion of (b) to (a)	43	58	63

Note that the concentration of chloride is more reduced than those of urea and phosphate

(c) In reflex diuresis the chloride concentration in the urine from the affected kidney should probably not fall below that in the plasma (about 0.6 per cent sodium chloride), so long as the chloride in the normal urine remains above this level (See Table II)

TABLE II
Urine in Diuresis* (Denervated Kidney)

	Chloride (NaCl)	Urea
	Per cent	Per cent
(a) Normal kidney	0.77	0.81
(b) Affected kidney	0.60	0.51
Proportion of (b) to (a)	78	63

* Not reflex since nerve connexions have been destroyed but electrolyte in origin and thus of similar type

Note that although the concentration falls in diuresis it does not fall below that of the plasma (about 0.6 per cent NaCl)

Urine from Damaged Kidney (Pyonephrosis)

	Chloride (NaCl)	Urea
	Per cent	Per cent
(a) Normal kidney	0.87	1.69
(b) Affected kidney	0.41	0.64
Proportion of (b) to (a)	47	38

Note that while the concentration of chloride from the normal kidney is higher than that of the plasma, the concentration of chloride from the affected kidney is lower than that of the plasma

(c) If the chloride concentration in the urine from the normal kidney is below that of the plasma, reflex diuresis should cause a higher chloride concentration in the urine from the affected kidney than exists in the normal urine (See Table III)

TABLE III
Urine in Diuresis (Denervated Kidney)

	Chloride (NaCl)	Urea
	Per cent	Per cent
(a) Normal kidney	0.50	0.75
(b) Affected kidney	0.60	0.21
Proportion of (b) to (a)	200	28

Note increase in concentration of chloride caused by diuresis when the normal concentration is lower than that of the plasma (about 0.6 per cent NaCl). Diuresis renders the urine more like the plasma

Urine from Damaged Kidney (Hydronephrosis)

	Chloride (NaCl)	Urea
	Per cent	Per cent
(a) Normal kidney	0.32	1.09
(b) Affected kidney	0.14	0.23
Proportion of (b) to (a)	44	28

Note that even when the concentration of chloride from the normal kidney is below that of the plasma the concentration of chloride from the affected kidney may be still lower

This statement and the previous one may require slight modification if there is a Donnan equilibrium at the glomerular membrane. None of the results yet obtained are of assistance in deciding whether any modification should be made

(d) In reflex diuresis the ratio of the urea concentration in the urine from the affected kidney to the urea con-

centration in the urine from the normal kidney should probably be somewhat greater than the corresponding ratio for creatinine (See Table IV)

TABLE IV
Urine from Slightly Damaged Kidney (Calculus in Pelvis Moderate Dilatation)

	Chloride (NaCl)	Urea	Phosphate (P ₂ O ₅)	Creatinine
	Per cent	Per cent	Per cent	Per cent
(a) Normal kidney	1.45	1.32	0.142	0.112
(b) Affected kidney	0.63	0.75	0.050	0.053
Proportion of (b) to (a)	46	57	35	47

Note injury shown by greater reduction in chloride than in urea. But urea is less reduced than either phosphate or creatinine

Urine from Severely Damaged Kidney (Pyonephrosis)

	Chloride (NaCl)	Urea	Phosphate (P ₂ O ₅)	Creatinine
	Per cent	Per cent	Per cent	Per cent
(a) Normal kidney	1.45	1.02	0.032	0.066
(b) Affected kidney	0.63	0.59	0.009	0.047
Proportion of (b) to (a)	43	58	63	71

Note that urea is reduced more than either phosphate or creatinine indicating some failure in urea excretion. Phosphate is sometimes almost much reduced in comparison with creatinine

In spite of numerous estimations the position occupied by phosphate has not been ascertained. The excretion of phosphate often bears a close resemblance to that of creatinine, but is apparently much more sensitive to changes in the kidney

The disturbance of one or more of these relations is regarded as indicating some degree of renal failure. The extent of the disturbance is of assistance in estimating the damage to the kidney

Finally, it should be stated that only about fifty cases have as yet been examined. All were patients of Professor Fullerton, who performed the ureteral catheterizations and obtained the specimens of urine. Most of the results are in harmony with the observations made by the surgeon, but a few apparent exceptions have still to be explained. Some possible sources of doubt may be mentioned. Clinical confirmation can only be considered satisfactory when the surgeon has had an opportunity of seeing the kidney, but in some cases an operation is not thought advisable or is refused by the patient, and in the remainder a complete examination can only be made when the kidney is sufficiently diseased to justify nephrectomy. Again, it must be borne in mind that the kidney which is taken as a normal control may not in reality be normal, although the blood urea is probably a safe guide in most cases. A less obvious error may be the cause of other misleading results. It is possible for fluid introduced into the bladder to travel up the ureter and dilute the urine which is passing down the catheter, particularly when the ureteral orifice has lost its valve-like character. Professor Fullerton has been careful to avoid this accident. Further, the urine from a very bad kidney can probably contain enough serum or pus to increase materially its low concentration of chloride, and perhaps enough to reduce the concentration of phosphate and other substances

It is fair to point out, in conclusion, that the examples given in this paper are chosen for the purpose of illustration. A general survey of the results justifies the application of principles discussed but at the same time emphasizes the need for further investigation, directed especially towards reflex diuresis in the healthy kidney

OPTIC NEURITIS FOLLOWING SPHENOIDAL SINUSITIS LOCATED BY THE DIFFERENTIAL EXPLORATORY TEST *

BY

PATRICK WATSON-WILLIAMS, M D LOND,
Consulting Surgeon for Diseases of Ear, Nose and Throat, Bristol
Royal Infirmary

Among the various lesions of the optic nerve that are known to occur as a result of sphenoidal sinusitis from infection by pyogenic organisms, definite optic neuritis may be one of the most important to trace to its source. In milder cases we believe that bacterial toxins alone suffice to cause relative scotoma and contraction of visual colour fields, but with a definite optic neuritis it seems probable that the infective organisms from focal sepsis of the involved sinuses penetrate the optic nerve sheath, as in the case of chronic sphenoidal sinusitis demonstrated after death by the researches of Pickworth.¹

On disinfection and drainage of the focal infection largely depends the saving of sight, and also, possibly, the averting of very grave sequelae.

When the infected sinus is anatomically normal in development—that is to say, when the two sphenoidal sinuses

FIG 1—Photomicrograph showing Gram positive micrococci in the dural sheath of an optic nerve (Pickworth)

are bilaterally symmetrical with a medial septum dividing the right from the left—the diagnostic location of the focal infection is relatively simple, and then the opening and draining of the infected sinus is fairly straightforward. Unfortunately the anatomical development of the sphenoidal sinuses and the posterior ethmoidal cells is very frequently most irregular, for one sphenoidal sinus may be very large, while the other is small, much undeveloped, and, so to speak, so tucked away as to occupy a small corner difficult of access. Again, the posterior ethmoidal cells may be exceptionally large, and extend back so as to occupy the space proper to a sphenoidal sinus, they may even extend backwards above the corresponding sphenoidal sinus, which then lies beneath the backward extension of its posterior ethmoidal cell.² When healthy, such abnormal anatomical conditions are immaterial, but when infected the actual location of the diseased sinus may be a matter of supreme importance, for although an infected cell be small and extraordinarily undeveloped, it may be large enough to breed millions of pyogenic organisms.

Formerly I fear I must have failed on many occasions to detect focal infections in such circumstances until I hit on a method by which the difficulties mentioned may be circumvented. Thus, for want of a better term, I speak of as the "differential test," as related in two remarkable examples I reported recently.³ In the case I now record this diagnostic method proved invaluable.

A man was referred to me by Dr Prosser James in December, 1927, with blurred vision and aching in his left eye. He had tonsillotomy at the age of 10 and a traumatic septal deflection when he was 12 and more or less recurrent nasal catarrh since then. No history of syphilis or gonorrhoea was present, but he had influenza in 1921. His eye troubles began with iritis in the right eye in January 1925, but he later developed left-sided iritis and was then seen by Dr Leighton Davies, who diagnosed optic neuritis.

Read in the Section of Laryngology and Otology at the Annual Meeting of the British Medical Association Cardiff 1928.

When I first saw him there was no nasal discharge, and in fact, examination of the nasal passages was negative with the sole exception of slight fullness of the minute vessels in the arch of the rhina, as seen by endorhinocopy. Such vascular fullness I had seen before in similar cases, and therefore, despite the absence of any other indication of nasal infection, the sinuses were explored with the suction syringe by my usual method.

The results obtained were as follows. The right antrum was clear and sterile.

The left antrum contained pus (*Staphylococcus aureus*). The sphenoidal sinus entered through the right nasal passage contained some blood, some crystals, but no organisms, the sphenoidal sinus entered through the left passage was sterile. The right posterior ethmoidal cell ($3\frac{1}{2}$ inches) contained blood from which *Staphylococcus aureus* was recovered. The left posterior cell ($3\frac{1}{2}$ inches) was clear and staphylococci were similarly obtained from it. But on applying the differential test it was proved that the sphenoidal sinuses entered through the right and left nasal passages were one and the same cavity! It followed that the other sphenoidal sinus had yet to be found by the use of a fresh cannula passed through the left nose, but directed more outwards entrance was effected into the small left sphenoidal sinus, from which blood-stained mucus was extracted. The differential test proved that this was a separate cavity from what had been previously entered, it being in fact the true but ill-developed left sphenoidal sinus which had at first been missed entirely. The essential focal infection causing the optic neuritis lay within this small left sinus, culture of its contents yielded a pure growth of streptococci. It was freely opened as well as the large right sinus, and the intersinus septum was clipped away so as to throw both sphenoidal sinuses into one cavity, the other infected sinuses were likewise opened through the nose.

The results of this operation and further course are best shown by citing the reports of Dr Leighton Davies, who writes:

When I first saw him in March 1925, he had very severe iridocyclitis of both eyes with double optic neuritis vision R 6/24 L 6/60. He had an x-ray examination of his teeth, and two were removed on account of abscesses at the roots. I had the patient's nose examined, and it was then reported free from infection. Some staphylococci were found in the mucus and for this he was given autogenous vaccines. He improved very considerably, and curiously enough, relapsed each time the vaccine was given up. By October, 1925, the iritis had entirely disappeared, and the optic neuritis was rapidly subsiding. In December I discharged him as cured. He started work in London but almost immediately began to relapse and was seen by Mr Fleming.

FIG 2—One cannula passed into the sphenoidal sinus through the right nasal passage and another through the left owing to abnormal overdevelopment of the right sinus both cannulae have entered this sinus, the small ill-developed left sinus has been missed. Proof of this is afforded by attaching the syringe to one cannula and quickly injecting sterile water, which appears escaping from the free projecting end of the other cannula.

FIG 3—By directing the left exploring cannula more outwards it has been made to enter the small left sphenoidal sinus previously missed. Consequently the two cannulae being now in separate cavities, water injected through the one obviously cannot escape through the other. Hence the proof of having entered both sinuses, one over large the other abnormally small.

By October, 1925, the iritis had entirely disappeared, and the optic neuritis was rapidly subsiding. In December I discharged him as cured. He started work in London but almost immediately began to relapse and was seen by Mr Fleming.

In March, 1926 he was seen again by Dr Davies when there was a distinct recurrence of the optic neuritis, but no iritis he had practically recovered by July, 1926, and in the meantime had had a tonsil enucleated. In November, 1927, he had another recrudescence of his optic neuritis. On no occasion has there been any scotoma, either relative or absolute, the fields were quite symmetrically contracted, and there was no enlargement of the blind spot.

On January 2nd, 1928, three weeks after the sinus operation, Dr Leighton Davies reported

"The vision has improved, and this improvement is associated with a very definite lessening of the optic neuritis which may be said to have practically subsided, though of course, the appearance of the discs is not quite normal. He has never made quite such rapid improvement."

On April 30th, 1928, three months after the nasal sinus operation, Dr Leighton Davies reported

"All the evidence of any congestion of the blood vessels of the retina has disappeared."

Timo plano can show whether the remarkable improvement following operation will be permanent. The main purpose of this communication is to describe the diagnostic technique for infection of irregularly developed sphenoidal and posterior ethmoidal sinuses, which has proved immensely helpful in several cases coming under my notice. I believe that it would have been impossible to detect the highly virulent focus of staphylococcal infection in this case except by the diagnostic method described. At any rate it is felt that such exploratory methods have the advantage of giving exact information as to the presence and location of an infection, or of its non-existence, in which case any useless operation could thereby be avoided.

PROSTATIC OBSTRUCTION

A SUGGESTED PROCEDURE FOR MORE ACCURATE DIAGNOSIS AND FOR THE TREATMENT OF SELECTED CASES

BY

HERBERT WILLIAMS, M.B., F.R.C.S.,

SENIOR HONORARY SURGEON, ROYAL SOUTHERN HOSPITAL, LIVERPOOL.
LECTURER ON CLINICAL SURGERY, UNIVERSITY OF LIVERPOOL.

The procedure described in this paper is suggested for the treatment of various types of prostatic obstruction, for which the methods of treatment at present employed are

not entirely satisfactory. It is devised particularly for dealing with small and moderate enlargements of the fibroid type and with local adenomatous projections on the vesical orifice. In most of the prostates of this type the pathological capsule is so ill developed, or is so adherent that clean enucleation is impossible. It is these cases that give so much trouble during operation and are followed by the least satisfactory results.

The technique here described serves two purposes: (1) the more accurate diagnosis of the type of prostate that is causing obstruction to the urinary outflow; (2) the destruction by electro-coagulation, under visual control, of the offending portion of the prostate. It entails the use of two instruments, which may respectively be termed the diathermy catheter and the suprapubic cystoscope. The catheter is passed per urethram, the bladder is then distended with water and the cystoscope passed into it by suprapubic puncture (Fig 1).

Description of Instruments

The diathermy catheter is exactly similar in shape to the ordinary gum-elastic coude catheter (Figs 2 and 3). It is 12 inches long and 22 Charrière in circumference. It consists of a metal tube insulated with special boilable lacquer. It is provided with two lateral eyes on the bend, and terminates in a detachable silver electrode. Various

shaped and sized electrodes can be fixed as desired. The proximal end terminates in a cylindrical chamber and connecting plug attached thereto at right angles. The chamber is provided with a stopcock, which controls the flow of the fluid. The catheter is connected to the diathermy machine by means of a rubber-covered cable with push-in connector.

The suprapubic cystoscope consists of a valved cannula (Fig 4) fitted with compression ring and rubber washer, trocar and cannula (Fig 5), and telescope (Fig 6). The size of the cannula is 21 Charrière in circumference and 4½ inches long. It is provided with a sliding guard, which can be fixed in any position. The optical system, owing

to its comparative shortness (6½ inches in length) and large diameter, gives a very brilliant image. It is, in addition, provided with wide angle objectives. The lamp is enclosed in the alignment of the telescopic sheath in order to ensure smooth passage through the cannula. It is connected to the battery by means of the usual switch, which is sprung into a groove behind the eye shield. Leakage at the proximal end of the cannula can be controlled by means of the compression washer in the cannula.

Anæsthesia

The procedure can be carried out under methylal or sacral anæsthesia combined with local infiltration at the site of the suprapubic puncture,

but in the main I have used general anæsthesia.

Technique

The patient is placed on the table in a moderate Trendelenburg position. The indifferent electrode of the diathermy machine is applied to his thigh preferably the right as the operator stands on his left side. The diathermy catheter is introduced and the bladder filled with sterile water from a funnel. It is filled to such an extent as to ensure that the peritoneal reflection is raised away from the pubis so as to allow of the introduction of the cystoscope into the bladder. A small incision, a quarter of an inch long is made through skin only, in the middle line, 1 inch above the pubic symphysis. The trocar, carrying

FIG 1.—The cystoscope should have been shown as entering the bladder nearer the pubic symphysis and in a vertical direction.

the two sheaths of the cystoscope, is thrust into the bladder in the same way as though for suprapubic aspiration. Immediately this is done the funnel is lowered and a few ounces of water are allowed to run out of the bladder. The object of this is to diminish the tension on the bladder wall, and so prevent the tendency for fluid to escape

FIG 2.

through the aperture, outside the sheath, into the space of Retzius, at the same time too much fluid must not be run out or the bladder wall will tend to retract off the sheath, thus leaving its distal end in the aforementioned space and not in the bladder. The trocar and inner sheath are now withdrawn, leaving the outer sheath in the

FIG 3.—Fig 2 enlarged to nearly two-thirds natural size. A, Lateral view. B, Detachable silver electrode. C, Connecting plug for diathermy machine. D, Stopcock. E, Orifice for filling bladder.

bladder. Water is prevented from escaping by the valve in the outer sheath. The proximal end of the withdrawn inner sheath is fitted with about 1 foot of rubber tubing and reintroduced through the outer sheath. Water from the bladder can thus be conveyed into a suitable receptacle. The funnel is now raised and water poured into it *ad lib*

FIG 4—Valved cannula

In this way a free current passes through the bladder and irrigates it in a most effective manner. As soon as the fluid escaping from the bladder is perfectly clear, the inner sheath is withdrawn and replaced by the telescope, which is passed with its fenestra towards the pubis. A pint or so of water is left in the bladder so as to allow a sufficient

FIG 5—Trocar and cannula

FIG 6—Telescope

volume of clear medium in which the end of the cystoscope can be moved. The tap of the catheter is turned off and the filling tube and funnel detached, the switch is attached to the cystoscope and the light turned on. The catheter is manipulated with the left hand and the cystoscope with the right. By moving the telescope up and down in its sheath, and by adjusting the proximal end of the whole instrument in the medial plane of the patient, the vesical orifice and the tip of the catheter projecting through it can easily be located. The appropriate degree of distension of the bladder must be maintained, for in this way only can the prism of the telescope be kept at some

distance from the base of the bladder. By adjusting this distance there is no difficulty in visualizing clearly the whole vesical aspect of the prostate. This is obviously a great advantage over the view obtained through a per urethral cystoscope, where only a segment of the orifice can be seen at a time, and that at very close quarters with its consequent magnification and distortion.

Examination of the Vesical Orifice and Vesical Aspect of the Prostate

The condition of the orifice, whether it is stenosed or deformed, and the precise macroscopic detail of the prostate, whether it is locally or generally enlarged, can be demonstrated. By adjusting the catheter so that its point just shows inside the bladder, and then moving it, it is possible to gauge the mobility or fixity of the vesical orifice. In the same way a fairly good idea can be formed as to the softness or hardness of the prostate. By using the tip of the catheter as a seeker, the prostatic urethra immediately below the orifice can be explored. Median bar formation, if present, can be demonstrated, together with the extent of its development and the degree to which a local adenoma projects into the urethra. With the information obtained in this way, in addition to that which has been previously obtained by the clinical, instrumental, and laboratory investigations, it is possible to give an opinion as to the nature of the obstruction to a degree of accuracy that is otherwise impossible.

Decision as to Further Procedure

With the instruments *in situ*, and with the information above obtained, the type of surgical procedure to be carried out is decided upon. If it is decided to do a one- or two-stage prostatectomy the suprapubic cystoscope is withdrawn. This done, leakage of fluid from the bladder takes place, rendering it less prominent than is desirable for making a suprapubic incision. There is no difficulty, however, in exposing the anterior surface of the bladder although it is not adequately distended. This being accomplished, an assistant applies the tip of his finger to the puncture in the bladder wall to prevent further leakage, and the bladder is redistended. The extraperitoneal fat and reflection are displaced upwards and the anterior surface of the bladder displayed. The assistant now takes his finger off the puncture, and the scalpel is immediately thrust into the bladder and the incision made. Further procedure is carried out as if the suprapubic puncture had not been made. On the other hand, if electro-coagulation is decided upon, the cystoscope is left *in situ*, the appropriate terminals are attached to the catheter and indifferent electrode, and the operation proceeded with as described below.

Method of Electro-coagulation

Controlling the cystoscope with the right hand, the prostate is brought into view, the catheter is manipulated with the left hand, the metal tip is embedded in the tissue to be destroyed, and the current turned on. At the beginning the current should be low, and should be gradually increased. The coagulating process is clearly seen through the cystoscope, and as soon as the whitening of the tissue occurs the current is turned off. The tip of the catheter is then embedded in another portion of tissue and the above procedure repeated. In this way substantial portions of the obstructing tissue and the whole of a small or medium sized adenoma can be destroyed at one sitting. A valuable feature of the procedure is that it is often possible to see the exact portion of tissue that requires destroying, and the coagulating process can be confined to that tissue only. If during the process of coagulation the medium in the bladder becomes clouded, the bladder must be washed through as above indicated and refilled with clear water.

The destruction of tissue having been completed the catheter is withdrawn from the bladder and replaced by a soft rubber or gum-elastic catheter of large size. I have found the Marion many-holed catheter particularly suitable for the purpose. The bladder is thus drained by the urethra for three days, so that the suprapubic puncture may become sealed. On the fourth day the patient is allowed out of bed.

This paper is not concerned with the general indications for prostatectomy. The same pre-operative investigation

is necessary whatever type of operation it is ultimately decided to perform. As regards pre-operative treatment, it is specially important that infection of the bladder should be combated as far as possible before treatment by electro-coagulation.

Indications for Electro-coagulation

Conditions suitable for treatment by electro-coagulation are the following:

- 1 Slightly enlarged prostates, especially those where there is only a local adenoma encroaching on or obstructing the vesical orifice, and obviously causing definite impediment to the outflow of urine. The indication is the stronger if at the same time the prostate is relatively small and fixed. It is in this type of case that electro-coagulation by this technique is of particular value.

- 2 Middle lobe obstruction.

- 3 Median bar obstruction.

- 4 The small fibrous prostate and contracture of the vesical orifice.

- 5 Flap formation resulting from previous operation.

- 6 Relief can be given to cases of obstruction in extreme old age those suffering from intercurrent diseases or those in which the renal function has deteriorated to such an extent as to render the ordinary operation for prostatectomy one of extreme gravity.

After-Treatment

For two or three weeks after operation a mixture containing hexamino and acid sodium phosphate is administered. During the first few days the patient complains of bladder irritability, and this may continue in diminishing degrees for about three weeks. This symptom can be alleviated to a certain extent by giving tincture of hyoscyamus. For about three weeks after electro-coagulation has been carried out sloughs of various sizes are passed in the urine, sometimes causing temporary obstruction to micturition. In one of my cases the patient was unable to pass the slough, having tried unsuccessfully to remove it by means of a Bigelow's evacuator. I adopted the following procedure. The bladder was distended with fluid and the cystoscope reintroduced at the site of the old scar. A lithotrite was passed and the slough seized and broken up under visual control. The larger portion of the slough was withdrawn in the jaws of the lithotrite and the remainder was removed by means of the evacuator.

Complications

Other complications that I have encountered are slight incontinence of urine, double epididymitis, and prevesical suppuration. In no case has there been any haemorrhage. One patient, aged 80, died of uraemia, a result that can hardly be attributed to the operation, since he was suffering from diabetes, was very anaemic from persistent haematuria, and had a non-protein nitrogen figure of 85 mg per cent. In the ordinary course of events I should not have operated on this patient, but as a last resort was induced to do so because of his very persistent and copious haematuria.

Early Results of Treatment

I have now used this technique for diagnosis alone or diagnosis and treatment in over fifty cases. Owing to lack of experience, bad selection of cases, and technical difficulties with the instruments, some of my early cases, though encouraging in their results, were not strikingly successful. Later results have improved substantially. Of the last twelve consecutive cases, one, referred to above, died, four cases, three of which came under my observation with complete retention, have been markedly benefited, inasmuch as micturition is now free and they have improved greatly in general health; they still, however, have some nocturnal frequency. The remaining seven cases may be classed as complete successes, inasmuch as they have urinary streams of good force and volume, which are passed without hesitancy or straining and without being followed by dribbling. They can retain their urine all night, and there has been a striking improvement in their general health.

As far as my present experience goes I am satisfied that, with this technique, detailed information about the prostate and vesical orifice obstruction can be obtained such as is impossible by any other means. It is therefore a definite aid to diagnosis. As regards treatment, I have had a high percentage of cases showing immediate relief, either complete or partial, but have not yet had them

under observation for a sufficiently long period to make any remarks as to the remote results.

I may incidentally mention that I have used this technique with complete success in three cases of papilloma of the bladder, in which the growth was either too large, or situated too near the vesical orifice, to be dealt with by perimethral diathermy, and have crushed a vesical stone with the ordinary lithotrite under visual control through the suprapubic cystoscope.

The instruments described above have been made for me by the Genito Urinary Manufacturing Company, and I have to thank Mr Schranz of that company for his technical advice and for the efficient way in which he has constructed the instruments to meet the requirements of the technique. I have also to thank my colleague Mr Stanley V Unsworth F.R.C.S. for his drawing of Fig 1.

STRANGULATED FEMORAL HERNIA

A COMPARISON OF VARIOUS METHODS OF TREATMENT,
WITH ESPECIAL REFERENCE TO END-RESULTS

BY

HAMILTON BAILEY, F.R.C.S.,
OILSON SCHOLAR SOCIETY OF APOTHECARIES SURGEON DUDLEY
ROAD HOSPITAL BIRMINGHAM

THERE still exists some doubt as to the advisability of relinquishing the old (lower) operation for femoral hernia. H. W. Carson¹ writes "I have been unable to find statistics of the end results of Lotheissen's operation." It is, perhaps, for this reason that in some quarters (to judge by the reports of disappointed candidates for the English Fellowship) the inguinal route for femoral hernia is looked upon with distinct scepticism, if not actual disfavour.

In order to determine the relative values of the various operative methods I have analysed my series of cases of strangulated femoral herniae, paying particular attention to the ultimate end-results. I have chosen *strangulated* cases because there are sufficient in each group to make a comparison. It would be manifestly unfair to compare the end-result of, say, a case of strangulation operated upon in the middle of the night by the older technique with an unstrangulated femoral hernia repaired at one's leisure by Lotheissen's method.

Disadvantages of the Lower Operation for Strangulation

The lower operation has been practised for years, and has saved thousands of lives, but it is beset with certain dangers and difficulties which, from time to time, have been recorded.

- 1 Resection and anastomosis within the limits of the wound is extremely difficult, and in many instances impossible. If resection is necessary laparotomy must usually be performed.

- 2 If the sac has been slit up in order to release a constriction high up in the neck, a loop of intestine may be reduced extraperitoneally. This is an error easily committed, and referred to by Jonathan Hutchinson, jun.²

- 3 The bladder is in more danger than when other methods are used.

- 4 The abnormal obturator artery, if cut causes embarrassing haemorrhage, whereas, when operating from above, the artery may be seen and is accessible.

- 5 The loop of imprisoned intestine may suddenly retract into the peritoneal cavity after the obstructing agent has been divided, and so prevent proper inspection unless laparotomy is performed.

It so happened that it was objection No. 5 which, in 1923, finally led me to abandon the lower operation.

A woman aged 28 had a strangulated femoral hernia of thirty hours duration. After Gimbernat's ligament had been nicked the obstructed loop before it could be inspected slipped back into the peritoneal cavity. Two days later general peritonitis supervened and laparotomy showed that a small patch of lifeless intestine had given way—evidently where the constricting band had been present. The patient died. I have never performed the lower operation since.

Lump returned	5

The Inguinal Route (Lotheisen's Operation)

The inguinal route for femoral hernia, while being technically a more difficult operation, is relatively immune to those dangers referred to above. Resection and anastomosis can be carried out within this area as readily as through a laparotomy wound. The only danger peculiar to this route is the proximity of the femoral vein, but if the simple precaution is taken of protecting the vein with the finger during the insertion of the deep sutures the danger fades into insignificance. It has been my privilege to discuss the merits of this operation with a number of the younger surgeons, some of whom had lately embarked upon actual operative work. When asked what they found to be the difficult part of the operation there was a general consensus of opinion that it was placing the sutures through the peritoneum and Cooper's ligament which overlies the ilio-pectineal line. This information emboldens me to describe a method of inserting these sutures which simplifies the operation. The femoral artery is located by its pulsation with the left index finger in the wound. The finger is now shifted 2 cm. to its inner side, where it will rest upon the femoral vein. Here the finger comes to rest and remains throughout this critical stage of the opera-

Method of placing the deep sutures referred to in the text

tion. In order that the ilio-pectineal line may be clearly visible good retraction is necessary, and a valuable instrument for this purpose is Sargent's retractor. Its shining surface helps also to reflect light into the depths of the wound. It is held by the assistant in such a way as to keep back both the internal oblique and the peritoneum (see figure). With a rather small curved needle mounted on a holder three sutures are passed through the peritoneum and Cooper's ligament overlying the ilio-pectineal line—the first being near the finger guarding the femoral vein and the last near the insertion of Gimbernat's ligament. After each suture has been placed the needle is removed, and the two free ends of the suture clipped together with a haemostat. The accompanying figure will make this stage of the operation clear. The detempered bendable needle, made by Philip Spencer of Redditch, which I described elsewhere,³ is very useful in passing these deep sutures. It may be bent up into a U shape, which materially aids matters when working in a confined space. Furthermore, it does not readily break if bone is encountered. The remainder of the operation is simple. Retractors and the guarding finger are removed. The free ends of the three sutures are passed through the conjoint tendon from its deep to its superficial surface, and tied in pairs. Thus the conjoint tendon is approximated to the ilio-pectineal line—the essential step in the repair by Lotheisen's method.

Analysis of Cases Treated by the Lotheisen Principle

Recurrence	2
Alleged recurrence, no hernia found on examination	1
No recurrence between one and six years after operation	22

Hey Groves's Operation

To those of us who were taught and brought up in the belief that to sever Poupart's ligament was permanently to weaken the abdominal wall Hey Groves's operation, which the originator described in 1923,⁴ was something of a surprise. His results, however, were so good as to compel attention. Personally I have used the method in only a small number of cases, but these have been the very worst subjects for any operation—namely, those who were so fat that Lotheisen's operation would probably have been very difficult, or those who were so ill or old that life was almost despaired of. The operation is quick and efficient, and the end-results are exceedingly good. It combines the simplicity of the older operation with the safety and good end-results of the new. Resection and anastomosis is not quite so readily performed through this exposure as in Lotheisen's operation.

Number of cases	7
Died	2
Untraced	1
No recurrence	4

Conclusions

1 Owing to the better exposure of the seat of the strangulation, Lotheisen's operation is less likely to be attended by operative accidents than the lower operation. Hey Groves's operation shares with Lotheisen's method this advantage.

2 The end results of both Lotheisen's and Hey Groves's operations are very considerably better than the old lower operation.

3 The technique of Hey Groves's operation is easier to understand and to master than that of Lotheisen's operation.

CANCER TREATED IN GENERAL PRACTICE BY COLLOIDAL LEAD

BY

ERNEST TALBOT, M.C., M.B., CH.B. VICT.

I was very much interested in the proceedings of the International Conference on Cancer, especially in the discussion relating to the treatment of this disease by lead salts. The pessimistic conclusions of some members who were present appear to justify a report of my treatment of two cases of cancer which, two years ago, were condemned as hopeless and inoperable. Although my experience has been limited to two cases only, the results have been both illuminating and encouraging.

CASE 1—Carcinoma of the Right Breast

The patient was 49 years of age and unmarried. In February 1924, I performed a radical amputation of the breast. The tumour was examined microscopically, and reported to be definitely carcinomatous. In June 1925, definite cancerous nodules appeared in the scar. The patient was now admitted to the Ashdon under-Lyne Infirmary, where Mr. Marcus Mamourian made a wide excision of the skin involved. In the following month she began to attend twice a week for x-ray treatment but in spite of this the cancerous nodules reappeared in the skin and extended rapidly. In May, 1926 the whole of the right anterior chest wall was one mass of cancerous nodules. A further excision was suggested to her but she declined to undergo any further operative intervention and x-ray treatment was continued. By this time the patient had become very cachectic and there was definite dullness on percussion over the upper right lobe of the lung and the mediastinum. She complained of difficulty in swallowing. There were undoubtedly secondary deposits of growth within the chest wall. As a last resort I began to give injections of colloidal lead. In June, 1926 the first injection of 1 c.cm. was given *intramuscularly* into the gluteal region. This was repeated every four days the dose being gradually increased until by the end of a month she was having 15 c.cm. After six months' treatment the scars on the chest wall instead of being fixed became movable, the nodules in the skin had disappeared, and she had gained 14 lb. in weight. There was no albuminuria, and the patient felt very much better. During this time 166 c.cm. of colloidal lead were injected into the gluteal region. In the next two months only one injection of 10 c.cm. was given. At the end of this period there was a reappearance of the cancer nodules in the skin of the right

anterior chest wall, and they continued to increase in number. Injections of 12 c.cm. were now given at intervals of one week, and in addition small injections were made locally into the cancer nodules. Again the cancerous nodules began to show what I regarded as a reactionary stage: the nodules gradually becoming red in colour then pink, and later still pale and glistening. A marked diminution in size was obvious and they ultimately disappeared altogether. The pain had gone from the chest, and she could breathe and swallow with comfort.

I continued the injections monthly for four months. Then three small nodules reappeared in the scar. The period between each injection was shortened again, and the nodules began to go through the same reactionary changes as before. In consequence the intervals were lengthened but apparently they were too long to keep the cancerous nodules under control as these increased in size and number. Again weekly injections were given, and it was necessary to persevere in this treatment for a further six months before all the nodules disappeared for the third time.

What appears to me to be the most striking fact in the course of the treatment of this case is that undoubtedly the cancerous cells can be definitely influenced and controlled for a considerable period by the injections of colloidal lead. As soon as the injections were diminished, either in amount or frequency, then did the cancerous growth regain its activity. In this particular case the effect of the injections on the cancerous nodules was apparent and clearly demonstrated.

During the whole period of twenty-seven months the total amount of lead injected intramuscularly was 804 c.cm. (or 12 grains). No albuminuria occurred at any time. So far there has been no further recurrence of the nodules in the skin, although only three injections have been made during the last two months, but her weight has decreased 6 lb. Whether the progress made in this case can be maintained remains for the present a matter of doubt.

The second case has been even more striking in view of the vast general improvement noted in the patient's health and appearance.

CASE II—*Carcinoma of the Rectum*

In October 1926 the patient a woman aged 41 was found to be suffering from an advanced carcinoma of the rectum. The surface of the growth was excavated and involved the whole circumference of the bowel. Its edges were raised, eroded and indurated and bled when examined. The growth was high up in the rectum (5 in. from the anal orifice) and the surrounding tissues were infiltrated. Marked cachexia was present her weight being 7 st 10½ lb. There was a definite trace of albuminuria.

In November 1925 I started a course of intramuscular gluteal injections of colloidal lead commencing with 5 c.cm. and a week later giving 10 c.cm. These were repeated about once a week the amount varying from 8 to 14 c.cm. Occasionally the patient complained of slight abdominal pain of a colicky nature. Sometimes the injections were followed by a small increase of the albuminuria. With the occurrence of slight abdominal discomfort or an increase of the albuminuria the amount of the lead injected was decreased or the interval between the injections lengthened. By this means she was enabled to take the injections without any real discomfort. At the end of six months treatment the patient had gained 14 lb. in weight. She said she felt very much better and certainly her statement was supported by her general appearance. Her appetite improved and the abdominal pain was practically absent. There had only been slight haemorrhage from the bowel. Examination at this stage indicated that the edges of the ulcer were softer the rectum itself could be moved more freely and it did not feel so fixed as formerly. The ulcerating process had extended downwards an inch further in the rectal wall and the lumen of the bowel directly above was narrowed and fibrosed. In addition to the intramuscular injections the patient was instructed to inject into the rectum two drachms of the lead solution with a urethral syringe this to be carried out once a week. During the first six months 300 c.cm. of lead solution were given intramuscularly.

The patient was very satisfied with her progress and anxious for further treatment. The very definite improvement in her general health and appearance and consideration of the rectal condition still present encouraged me to persevere. The injections were omitted for one month and then continued varying the interval between each injection or the amount given according to the response.

The patient has been under treatment for twenty-two months and has gained 24 lb. in weight. The improvement in her looks has been so marked that some of her friends scarcely recognized her as the same woman and she is now able to perform her household duties.

Rectal examination indicates that the ulcerated edge of the growth has extended downwards much further and practically involves the anal canal. The lumen of the rectum is greatly reduced and is about the diameter of a lead pencil. The rectal wall itself appears to have been replaced by a solid mass of fibrous tissue. The rectum is not so fixed as before and can be moved more freely over the sacrum.

The question which arises is: Will the growth be defecated and exterminate itself when it reaches the anal margin? Should this be the case and the glandular involvement

(which undoubtedly must have been present earlier) have been influenced in a similar manner to the rectal growth, then one might look hopefully for a cure of the condition. It seems remarkable that with such diminution in the size of the lumen of the bowel the patient has not developed obstructive symptoms. With this in mind she has been kept on a modified though nourishing diet, and has taken regularly sufficient casena and liquid paraffin to ensure a dark action of the bowels. There have been no bladder symptoms. The amount of albumin in the urine has varied slightly from time to time, but even now is no greater than when the treatment was begun. General tonic treatment has been given in the form of Ca ferri iod and Ca glycerophos co. The total amount of colloidal lead given intramuscularly to date is 632 c.cm., or 10 grains of lead.

The first patient had very small and insignificant superficial veins of the arm, and it would not have been possible to give a prolonged series of injections, so the intramuscular method was substituted. This patient stood the procedure so well that I decided to repeat the method with the second case. Both patients stood these injections well, and by giving them alternately into either buttock no untoward results occurred locally, except that the site of injection sometimes remained a little indurated. Occasionally slight tenderness was complained of for a day or two. The patients were treated at the surgery, and were advised to rest quietly for twenty-four hours, after which time they went about as usual.

Generalization regarding two cases only is not possible, but the results achieved and the observations made in the case of the secondary carcinoma of the breast, where the growth could be kept under direct observation, emphatically proves that lead has a very definite and detrimental action upon cancer cells. Intramuscular injections appear to produce the desired effect without causing acute toxic symptoms, and the patient can be brought more gradually, and with greater safety, under the influence of lead.

The encouraging response in these cases appears to warrant a more general consideration of the treatment. The lives of these two patients have been undoubtedly prolonged and made more comfortable and hopeful. One can only trust that by reporting these cases a little further encouragement may be given to the pioneers in the fight against cancer with lead salts. Moreover, the treatment does not appear to merit such wholesale condemnation and adverse criticism as it has recently received.

TREATMENT OF HAEMORRHOIDS BY THE GALVANO-CAUTERY

BY

W. S. WHITCOMBE, M.D.,

LONDON

In October, 1925, I read a paper at a meeting of the Hæmorrhoid Society on the treatment of hæmorrhoids by the galvanocautery. A synopsis of it was published in the *British Medical Journal* of November 28th, 1925 (p. 992), and attracted a good deal of attention. It seems advisable therefore that I should make public the new experiences I have encountered during the past three years, with notes of exceptional cases.

My records during this period are in entire accord with the opinion I expressed in 1925—namely that the method I then advocated is the best means of curing hæmorrhoids known at the present time, it has been adopted by many of my colleagues in the treatment of their own patients.

The subject-matter of this communication falls into three categories:

General Observations

The rotating speculum made to my design by Messrs. Allen and Hanburys has proved of inestimable value. It ensures quick accurate and neat work. It is not necessary to withdraw this speculum and reinsert it as had to be done when the older patterns were used. The cut-away gap can be revolved in a second to catch any portion of protruding mucosa which may drop into it.

I find however that for some cases in which hæmorrhoids are high up, above the internal sphincter, it is

necessary to use a 3-inch speculum. The original one was only 2½ inches in length, the extra half-inch makes all the difference. The cautery humors will last for months if care be taken to prevent them from being overheated, they will stand a bright red heat, but not a white heat.

In those patients who have a very rigid external sphincter it is necessary to dilate the anus gently before introducing the speculum, for reasons given later. I am unable to understand the assertions of those who state that the rectal mucosa is insensitive. The comment of a great physiologist may be recalled, though his wording was more blunt and humorous, the gist of what he said was as follows. It was a wonderful forethought on the part of Nature to endow the rectal mechanism with such a delicate sensitivity that we are able to distinguish between gaseous and solid matter.

Recently, when canterizing a portion of the mucosa, 2½ inches above the anus, in a highly strung lady, she flinched at every puncture and complained of pain, although I had previously given an injection of eucaine and adrenaline. I admit that the rectal tissues are extraordinarily insensitive in some people, but in very few.

Patients who show a tendency to arterial spouting during treatment should be carefully questioned as to any haemophilic history, such as is evidenced by free bleeding after dental extractions, and precautions similar to those mentioned later should be adopted. When the puncture caused by so fine a point as a Schimmel's needle excites arterial bleeding it is obvious that one must be on the look out. It does not follow that blood conglutates inside the vessel because it is seen to clot outside.

Uncommon Varieties

The Congenital Pile—This is not a true haemorrhoid, but is of the nature of a polypoid growth. It is covered with adventitious tough epidermis showing chamois-like follicles, and is usually about the size of a small walnut, there is a long thin pedicle which arises from the mucosa above the internal sphincter. It is extruded before each defaecation and causes great distress, but it does not bleed. For such a condition I use a flat-bladed cautery burner, and cut through the pedicle as near its base as possible, there is no bleeding, and a perfect cure is effected immediately. I have seen three such cases since 1925.

The Conglomerate Haemorrhoid—This is the largest of all, being composed not of one but of many convoluted varicose veins, with an arterial supply in proportion. It arises almost invariably from the anterior wall, and has a wide base, it is irregular in shape, and is about the size of a large French plum. It comes down with every motion or with any strain during the daily work, replacement is difficult, and causes great distress. The cases which I have seen were in men with enlarged prostate, more rarely it is found in women with a retroverted uterus. In either case it is obvious that the pressure from above, by these organs, interferes with the venous return flow.

In one case the worst I have ever seen there were large oedematous masses of prolapsed mucosa surrounding the anus, which gave the appearance of a small jelly fish. A large ulcerated pile was in the centre. The patient, a man aged 45, had had to wear a diaper for months owing to the constant profuse mucopurulent blood stained discharge. His condition was pitiable, and it had affected his general health to a very marked extent, he was pallid, very anxious looking and was greatly distressed. I had grave doubts as to whether I could cure him, however after firm pressure on the protruding mass, which reduced the oedema considerably, I was able to destroy the largest and the most ulcerated of the haemorrhoids. In this case I had to use the cautery on about a dozen different occasions, but the prolapse gradually subsided and in two months the patient had completely recovered. Two years have elapsed, and he remains perfectly well.

Complications

These, fortunately, are very rare. Until 1925 I had not observed any condition which could be called a complication, since then, perhaps owing to a large increase in the number of patients treated, I have noted the following.

Fissure—It is a pity that this term is still used, for patients do not understand its very slight significance, and when told that they are suffering from fissure are apt to think that it is some horrible rectal disease, instead of

which it is merely a slight split like a cracked lip. I cannot understand why it should be considered necessary to magnify this condition into one necessitating operation, as is so frequently done. Three of my patients, complaining of considerable discomfort in the anal region, showed on examination after treatment that the pain originated from a slight laceration at the edge of the anus, all had very rigid sphincters. It is quite easily cured by gentle scraping after an application of cocaine and painting with the solution of crystal violet and brilliant green, or with scarlet red ointment.

Fistula—One case, the only one I have ever seen, occurred about three years ago, the why and wherefore I am at a loss to know. If I did not use Schimmel's needles, and if I did not make it an invariable practice to sterilize my own hypodermic syringe, I should have attributed the infection to the injection of the local anaesthetic used. As I invariably employ glass ampoules of the latter, the anaesthetic itself could not be blamed. This fistula was very small and quite near the anus posteriorly. It healed at once after incision and scraping, and scrubbing with the crystal violet solution. This patient completely recovered forthwith.

Haemorrhage—As a rule there is none, with the exception, perhaps, of a streak of blood during defaecation. I have, however, had three cases in which considerable secondary bleeding occurred. Such secondary haemorrhage is very worrying to the doctor and also alarming to the patient. In each of the three cases the bleeding started quite suddenly about the fourth day after the first application of the cautery. In one case there was a clear history of haemophilia, and I do not doubt that the other two patients had also haemophilic tendencies. Haemophilic serum was given freely, and the rectum was packed. These measures proved successful, and there was no return of the haemorrhage. Since these cases occurred I have made it a practice to question every patient carefully, and, if considered necessary, to give a full dose of normal serum before treatment. Erythrin by the mouth is also useful, and measures may be taken to increase the calcium content of the blood.

Pain—This symptom is only experienced in cases where the extremely sensitive nerve endings in the skin are involved, as in haemorrhoids which are partially covered, even ever so slightly, with perianal skin. When this condition is found the patient must be warned that there may be some after-pain and a sedative suppository be prescribed. I advise the following:

Morphin sulph	gr 1/2
Cocain hydrochlor	gr 1/2
Gelatin melle q.s. ut fiat suppos unum	

Sig: A whole suppository, or half of one, to be used when required.

The pain, in the case of accidental fissure, yields at once to cocaine ointment.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

ABDOMINAL FRICTION IN PERITONITIS

It does not seem to be mentioned in textbooks that in early peritonitis there may be a subdiaphragmatic friction exactly resembling the friction of pleurisy. The first time that I heard it was in a case of perforated duodenal ulcer, where there was no vomiting, but pain and a well-marked friction rub on the right side from the sixth rib down to the costal margin. This caused some delay in operating, being mistaken for pleurisy, but a few hours later the friction was replaced by silence and loss of liver dullness owing to gas from the perforated duodenum. Since then I have heard this abdominal friction on the left side over the stomach in a case of very acute cholecystitis, and, quite recently, on the right side in peritonitis due to a perforated typhoid ulcer, in that case the friction extended a couple of inches below the costal margin.

WALTER BROADBENT, M.D. Cantab.,
F.R.C.P.

Brighton.

INJECTION OF VARICOSE VAINS WITH CARBOLIC ACID

The cure of varicose veins by the use of sclerosing injections has now replaced the extensive and often mutilating operations of the past. Since Southwate popularized intravenous injections in this country many thousands of cases have been cured, but the method cannot yet be said to have reached finality. There are certain objections to all the sclerosing solutions in use, sodium salicylate and saline solutions give rise to very considerable pain when injected, gumme may produce abortion in pregnant women, and pain and excessive loss at the menstrual periods, glucose seems quite unreliable. Further, in each method the injected substance is poured into the general circulatory system, which for the treatment of a purely local disease seems open to grave objection. In rare cases of marked idiosyncrasy even life itself may be endangered. A sclerosing substance which will remain localized at the site of injection should be free from objection.

For some time past I have discarded the solutions in general use and instead inject from two to four minims of undiluted acid carbohc liquid (B.P.) into the lumen of the affected vein. Only a small amount of acid is required, 4 minims is sufficient to obliterate a large varicose saphenous vein. The acid destroys the endothelial lining, and is then at once locked up in the clot which forms immediately. Since adopting this method, which I have now used in a very considerable number of cases, I have not experienced a single undesirable result, local or general. Providing the injection is made with due care ulceration never takes place. The injection in all save a very few susceptible persons is practically painless, the usual complaint, if any, being of the prick of the needle. The vein almost immediately hardens. Four to eight veins may be injected at a sitting with complete safety although many patients prefer the lesser number. From twelve to thirty-six hours later the usual inflammation sets in, but even this seems to be less severe than with other injected solutions. This inflammation dies down after a few days and the vein shrinks up, often with an almost dramatic rapidity. Sometimes a week after the injection it is difficult to find the remnants of the vein.

When very large masses of varices are present as often in the calf, a crepe bandage may be applied after the injection. This partially obliterates the vein, and only permits a flattened clot to form, thus saving some unsightly results. Veins below the knee are best injected with the patient standing for the large veins in the thigh a descending injection is best.

The only instruments required are an ordinary 1 cm. Record syringe and a No. 2 short-bevelled steel needle $1\frac{1}{2}$ inches in length. Messrs. Allen and Hanbury's now keep these in stock. After drawing up the carbolic acid into the syringe the needle must be carefully wiped with cotton wool, otherwise in some susceptible people a nasty skin burn may be caused by the coming of acid on the outside of the needle. The needle being of rather large calibre it is wise to insert it at least half an inch away from the vein, and to enter the vein obliquely, if possible from underneath. This prevents any of the acid and blood reaching the skin along the needle track. When the vein is entered a little blood is aspirated through the needle until curled up clot is visible in the syringe. The piston is then pushed home, driving the clot and acid together back into the vein. In occasional difficult cases where the vein cannot be entered a drop of acid may be deposited on the under surface of the vein. This proves quite effective. On no account should any of the acid be injected on the surface of the vein next the skin or ulceration might easily occur. The needle is not removed for some seconds after the injection. On withdrawal pressure is kept up for a few moments over the needle track, thus effectually sealing it.

There seem to be no contraindications to this method. One obtains 100 per cent. of cures and no special syringes or other appliances are needed. Veins do not become immunized to the acid, as they often do to the other solutions in use, rather they seem to become more susceptible after each treatment. Obviously there is no danger of introducing sepsis into the clot.

DECIDUAL FORMATION IN THE OVARY DURING PREGNANCY

At a meeting of the North of England Obstetrical and Gynaecological Society held in Manchester on October 26th, with the president Mr. LEITH MURRAY (Liverpool), in the chair, Dr. D. DOUGAL (Manchester) gave an account of decidual formation in the ovary during pregnancy.

Dr. Dougal said that when performing Caesarean section or some other operation on the pregnant uterus he had often been struck by the peculiar appearance of the ovaries. The outer surfaces were streaked or mottled with a reddish brown material, and this, on microscopic examination, was seen to be composed of irregular outgrowths of connective tissue apparently derived from the tunica albuginea. The cells of this tissue frequently showed a decidual reaction. The ovary which he was now exhibiting was removed, together with a three months gravid uterus, from a woman with severe mitral stenosis, in whom it was considered advisable to terminate the pregnancy and perform some sterilizing operation at the same time. Both ovaries from this case showed the streaked appearance he had described, but in this particular one the condition was more marked and almost resembled a papillary growth. Its appearance on microscopic examination was that of typical decidua. The decidual cell was generally described as being large and oval, with faintly granular and vacuolated protoplasm and a prominent nucleus. Both nucleus and protoplasm stained faintly with the usual reagents. The cells themselves lay in a fibrillar matrix and around them were numbers of small round cells. Wilfred Shaw gave the classical characters of decidual formation as the presence of decidual cells together with round cells in a fibrillated matrix. The decidual cell was normally and properly found in the endometrium, where it was derived from the stromal cell, it could be demonstrated in the premenstrual phase of menstruation and in uterine and extrauterine pregnancies. Its distribution, however, was much wider than this, for it had been found in the muscle wall of the uterus, the cervix, Fallopian tubes, ovaries, pelvic peritoneum, appendix, omentum, and various other organs—ectopic decidual cells. This distribution closely resembled that of endometrioma, and if Sampson's theory as to the causation of these tumours was accepted it was tempting to ask if the ectopic decidual cells had any relation to them. Wilfred Shaw did not accept Sampson's views on endometrioma, and explained the distribution by suggesting that the property of decidual formation was not inherent in all cells but only in those derived from the sub-coelomic connective tissue. In true cases of endometrioma, whether in the uterus, recto-vaginal space or ovaries, a decidual reaction could generally be demonstrated during pregnancy. The occurrence of decidual formation in the ovary was stated to be very constant during pregnancy, whether the latter was uterine or extrauterine, and Wilfred Shaw and others had found a similar change during menstruation. The cells were arranged usually in groups in the connective tissue of the tunica albuginea and formed either nodules projecting from the surface of the ovary or flattish areas. More rarely the cells were found deep in the cortical stroma. In the case of ovarian pregnancy which he had described there was a very well marked nodule of decidual cells immediately under the surface of the ovary. It was formerly supposed that decidual cells were produced through the local stimulus of the embedded ovum but this view was untenable at the present time for it was now realized that the decidua of pregnancy was merely a further development of the decidua found during the premenstrual phase and was developed whether the ovum was in the uterine cavity or elsewhere. As a matter of fact pregnancy was not necessary for the formation of a decidua at all for Loeb had been able to produce this structure in rabbits during pseudo-pregnancy by injuring the lining of the uterine cavity. This observer's experiments appeared to show that the primary factor in the formation of the uterine decidua was the presence in the circulating body fluids of

a hormone developed in the corpus luteum. This hormone sensitized the uterine mucosa and other cells, which then formed a decidua in response to any non specific irritation.

The President described the occurrence of islands of decidual tissue on the peritoneal surface of the uterovesical reflexion. He showed microscopical sections of such an island which though easily removed by light pressure, left a raw bleeding surface behind.

Mr W. W. KING (Sheffield) said that he had excised one of these rusty-looking ovaries at a Caesarian section about the time of the publication of Wilfred Shaw's paper and had found decidual cells both on the surface and in the substance. The latter were of special interest, as they appeared to be either a decidual change in the connective tissue cells of an old corpus luteum or a metaplasia of the luteal cells themselves into decidual cells. He showed slides illustrating the presence of the decidual cells arising in the corpus luteum, but confessed that he was unable to determine from which type of cell they arose. He had seen similar rusty-looking ovaries in the course of operations upon fibroids, but on section these only showed connective tissue and mesothelial cells derived from the peritoneum.

Sarcoma of the Uterus

Dr DOUGAL described a case of sarcoma of the uterus in a patient 58 years old, who had been married thirty-three years and had borne one child twenty-five years previously.

Fourteen years ago one breast had been removed for carcinoma and three years later a similar growth was removed from the opposite breast. The menopause occurred at the age of 55, after this there were one or two irregular periods, and then nothing was seen until about seven months before the operation. During this period of seven months she had had a constant blood stained and yellowish discharge. She complained of no pain, the discharge being the only trouble and the one for which she sought medical advice. Her general health had not been good for six months and her appetite was poor. On examination the uterus was found to be much enlarged and to form a firm uniform tumour reaching almost to the umbilicus. A diagnosis was made of carcinoma of the body of the uterus or carcinoma with fibroids, and she was admitted immediately to hospital. The uterus was removed with both appendages and one or two enlarged glands were excised from the iliac groups. The uterus was about the size of a five months pregnancy and contained a large necrotic growth in its cavity there were also one or two small fibroids. The hysterectomy was perfectly straightforward. The patient made an uneventful recovery and went home at the end of three weeks. The uterus measured 7 inches in length, 5 inches in width and 4 inches antero-posteriorly. There was a fibroid about the size of a walnut low down on the right side and one or two smaller fibroids elsewhere in the wall of the uterus. The enlargement of the uterus was due to a large necrotic tumour which filled the cavity and contained areas of haemorrhage. Microscopic examination allowed the growth to be a round-celled sarcoma, so presumably it originated in the endometrium. Three months after discharge from hospital the patient complained of severe sciatica in her right leg. On examination Dr. Dougal found a definite fixed swelling in the right side of the pelvis and advised that there was nothing more to be done except to relieve her pain. However, as her own doctor was anxious that some further treatment should be tried she was readmitted and Dr. Birckett applied radium by needles inserted into the right vaginal fornix. This treatment did not improve matters, for within four weeks she had become so ill that she had lost the use of her lower limbs. She was admitted to the Christie Hospital, where she died in about a fortnight's time four months after the uterus was removed. Dr. Powell White who made a post mortem examination reported that there was a recurrent mass of growth occupying the pelvis and infiltrating the vagina and bladder giving rise to acute cystitis. The growth had extended along the walls of the pelvis behind the rectum but the latter was not infiltrated. The growth had involved the upper part of the sacrum and the adjacent portions of the ileum on both sides and had invaded the spinal canal producing compression of all the roots of the cauda equina. There were no enlarged glands and no metastases. The sites of operation in both breasts were quite sound. Microscopically the growth was a small round-celled sarcoma and was infiltrating the bladder, muscle walls, nerves, and bones.

In Dr. Dougal's experience sarcoma was a very rare tumour; he had only seen four cases during the last three years. The majority of the patients had been elderly women, past the menopause. A point of interest in the present case was the extraordinary infiltrating power of the tumour, which had largely destroyed the osseum and lower part of the spinal cord.

Dr. BRENTNALL also showed a specimen of sarcoma of the uterus. The growth was largely submucous, apparently in process of becoming polypoid, although in places it reached almost to the peritoneal surface of the uterus. It was nowhere encapsulated, but macroscopically it was of the circumscribed variety. Dr. Brentnall thought it was

a primary sarcoma of the uterine muscle, arising as such *de novo*, and not in a pre-existing fibroid. In the fresh state the tumour was soft, and the cut surface presented a yellow and lobulated appearance. There were no haemorrhages into the tumour, and no evidence of gross necrosis or the formation of cystic spaces such as were described as occurring in these tumours. Sections of the tumour showed it to be composed of solid masses of small round cells. There was nothing to suggest a fibromyoma. The patient was alive and well two years after operation.

Dr. DONALD discussed the question of the diagnosis of sarcomata, and the President commented on the extreme malignancy of the tumours in his experience.

Red Degeneration in Fibroids

Dr. DOUGAL, who described two cases of red degeneration in fibroids, thought it was obvious that the acute pain in these cases must have been due to the high tension within the capsule of the tumour, and that this in turn must have resulted from interference with the return blood flow. Fletcher Shaw and Lorth Murray had both agreed that this interference was due to thrombosis, but was not the process of thrombosis too slow to account for the sudden onset of the symptoms? Might there not have been some other factor which suddenly held up the return circulation, and was followed later by a secondary thrombosis after stasis had occurred? In the case of a twisted ovarian cyst this factor was readily demonstrated in the pedicle, but the great majority of red fibroids were intramural, and the only way in which the circulation could be suddenly obstructed would be by spasm of the surrounding uterine muscle. This might easily be set up by the irritation of the tumour acting as a foreign body, in the same way that the muscle of the gravid uterus sometimes developed a spasm—tonic contraction or contraction ring—as a result of a similar stimulus. The uterine muscle was more sensitive during menstruation and in the gravid state, and it was known that degeneration was more frequently met with at these times. It might be urged that there was no blood extravasation in the tumour in the case of red degeneration, whereas in a twisted ovarian tumour this was present in the cyst wall and in the loculi. The consistence of a fibroid, however, was much tougher than that of an ovarian cyst, and the vessels were therefore less likely to rupture. Fletcher Shaw had divided fibroids of a red colour into two pathological classes, thrombotic and angiomatous, and was of opinion that cases with clinical symptoms belonged to the former group. In many of these thrombotic cases, however, the symptoms were few or very slight, so the process of thrombosis did not completely explain the very acute symptoms he had described. Two days previously he had removed a typical red fibroid associated with pregnancy, and the patient had never complained of any pain.

Rupture of the Uterus

Dr. GERRARD (Manchester) described a case of rupture of the uterus.

The patient was admitted to hospital after the first twin had been delivered by natural forces, the second twin was impacted by the hand and cord being prolapsed. Attempts at delivery by version had been made without success. On admission the patient was in good condition with a pulse of 102. On abdominal examination the most obvious feature was the prominence of a foetal hump to the left of the umbilicus. This was easily identified as a leg, and the possibility of rupture of the uterus was discussed but was ruled out owing to the excellence of the patient's general condition, the suggestion being made that the uterine wall was extremely thin from distension by twins and hydramnios. The pelvic measurements were normal. Vaginal examination revealed a prolapsed hand and foot and an umbilical cord which was not pulsating. There was no bleeding. Under anaesthesia delivery of the child was effected without difficulty by traction on the presenting foot. There being no abnormal amount of bleeding after this manoeuvre the patient was left to deliver the placenta herself. On palpation of the uterus abdominally a rather puzzling state of affairs was found. The impression obtained was that the placenta had left it but downward pressure failed to push it out from the vagina and on drawing the uterus upwards the cord shortened. It was therefore presumed that the placenta was still *in utero*. After an hour's time there was no sign of the placenta, the patient's condition was not too good but there was no cause for alarm. After two hours she was beginning to show signs of shock and as there had been a little bleeding a further anaesthetic was given to allow manual removal to be performed. On introducing the hand into the uterus no placenta

could be found and one became aware of a large rupture of the anterior wall of the lower segment. The cord was therefore cut off short, the vagina carefully swabbed out with antiseptics and packed with sterile gauze, and the patient who was by now in rather a critical state, was removed to the theatre. On opening the abdomen the missing placenta was found in the region of the spleen. There appeared to be quite a negligible quantity of blood in the abdominal cavity—less than an ounce in fact—and there was no bleeding from the torn uterus which was well contracted, but it was deemed advisable to perform hysterectomy. This was done rapidly by the ordinary subtotal technique, except that an opening was left in the cervix for drainage. The pelvis was peritonized, the abdomen mopped out and the abdominal wall sutured in layers, no drain being left in. An intravenous saline injection was given and the patient was treated for shock on the usual lines but she was placed in "Fowler's" position as soon as it was deemed advisable. She had a swinging temperature, and some vaginal discharge for a week following operation but the abdominal wound showed no signs of suppuration and the patient was able to proceed home within three weeks.

Dr Gerrard said that the points of interest in this case seemed to be the following: (1) The small amount of haemorrhage, due presumably to the situation of the tear. By way of contrast he cited a case which he saw about a month later, where a woman was admitted to hospital with a breech born as far as the head, which was hydrocephalic. While the instruments were being boiled the patient suddenly cried out, collapsed, and died within ten minutes. A post-mortem examination revealed a tear through the uterine artery. (2) The fact that one of the child's legs was probably projecting through the rupture into the abdominal cavity when the patient was admitted would have indicated the correct diagnosis had her condition not been so good. (3) That the placenta and membranes should be delivered into the cavity of the abdomen.

Formation of an Artificial Vagina

Mr W W KING (Sheffield), who described the formation of an artificial vagina, said that the procedure adopted was based upon one originally described by Graves and recently modified by Davies and Cron. The methods of forming an artificial channel in cases of congenital or acquired absence thereof comprised (1) those of the Baldwin type in which the small intestine was used, (2) the Schubert type in which a segment of rectum was employed, and (3) those in which the vagina was fashioned out of vulval flaps. The Baldwin operation gave very good results from a functional point of view, but it had a heavy mortality amounting to 17.5 per cent. Operations which employed portions of the rectum gave nearly as good functional results and had the much lower mortality of 3.3 per cent. The objection to the method was that it was liable to be followed by incontinence of faeces or faecal fistulae. Many women would risk a 3.3 per cent. mortality even for a plastic operation to avoid a nullity suit, but all would prefer a life of celibacy to a life of faecal incontinence. Because of these objections, and perhaps also on account of a certain repugnance to the idea of using portions of the intestinal tract for intercourse, attention had been focused upon the flap methods of operation. Papers had recently appeared by Frank and Geist and by Davies and Cron which described operations of this type. The speaker had no experience of the former operation, which involved raising bridge-like flaps from the thigh and transferring them by three successive operations to the recto-vaginal space to line the new canal. He had had, however, the opportunity of performing the operation of Davies and Cron. He had found certain difficulties in the technique, and the result was a vagina which was rather small and too short. As a result he had devised a technique which he had had the opportunity of employing in one case with apparent success, though sufficient time had not elapsed to speak of the final result. The steps of the new operation were described in detail and illustrated by lantern slides, from original drawings.

Various Cases

Dr K V BAILEY (Manchester) described a case of melanotic sarcoma of the vagina with secondary deposits in the inguinal glands.

Examination disclosed a large fungating mass the size of a coconut protruding from the vagina. This mass was attached to the region of the left labium minus and left vaginal wall over a relatively small area, though one could not say that it was pedunculated. A further smaller growth sprang from the region

of the posterior vaginal wall, near its junction with the perineal skin. There was also a hard nodular area in connexion with the under surface of the urethral orifice. In addition to these growths the vulva showed scattered irregular areas of a definitely gangrenous nature. These spread as far upwards as the mons, downwards to the anal canal and laterally to the skin covering the adductor muscles. In view of the obvious local discomfort Dr Bailey decided to excise the vulva as far as possible—thus removing the main mass. This he did on June 7th. The base of the main mass was included in the excision, as was also the smaller perineal growth. It was impossible to extirpate totally all the gangrenous areas, and he did not prolong the operation in order to excise the nodule from the urethra. To his intense surprise the incisions healed in ten days by first intention. Moreover, the scattered gangrenous areas cleared up within two weeks and the patient appeared much better. Meanwhile he had examined the growth microscopically and ascertained its nature. Such was the startling nature of the patient's improvement and the completeness of the healing that he decided to deal with the involved glands and the urethral nodule. The second operation was performed on July 17th, less than six weeks after the first. The nodule below the urethral orifice was found to penetrate the wall of the urethra and a much larger prolongation of it almost completely blocked the urethral lumen. This, of course, caused the difficulty in micturition. The urethral orifice was reconstructed after removal of this growth, which 'ebbed out' like a small gland. The involved glands in both inguinal regions were then removed, and the fatty tissue cleared out. Complete healing again took place and the patient was discharged from hospital two months after admission without a sign of the growth. Microscopical examination showed that the tumour was a melanotic sarcoma.

Dr Bailey added that he had seen the patient again on the day before the meeting. There was a small recurrence in the region of the left vaginal wall, close to the incision. The patient felt well. He thought that radium would now have to be employed.

Dr DONALD (Manchester) described a case of ovarian pregnancy.

A young married woman 22 years old was admitted to the Royal Infirmary with acute abdominal symptoms. There had been irregular uterine haemorrhage for about six days and previously to this a period of six weeks amenorrhoea. The acute abdominal symptoms commenced two days before her admission, the pain being worse on the right side. There was also definite shoulder pain. The patient was acutely ill, and presented the typical appearance of a ruptured extrauterine gestation. The abdomen was found to be filled with blood. The right ovary which was much enlarged and contained a blood clot was removed. The uterus and other ovary were quite healthy. The specimen consisted of the right ovary and tube. The ovary was enlarged and measured 3 in by 2 in by 2 in. It contained two cystic cavities, the larger being a typical dermoid cyst with sebaceous contents and embryonic process, the smaller a typical blood mole. Sections of the mole showed chorionic villi quite definitely. The tube on this side was perfectly healthy. The specimen was a good example of ovarian pregnancy and was of added interest because of the associated dermoid tumour.

Dr DONALD (Manchester) showed a specimen of uterus sub-septus removed from an unmarried lady, aged 56. She had had no regular periods for six years, but for some months had frequent uterine haemorrhage. On examination under an anaesthetic the double condition was not made out, as the uterus was small, and no definite tissue was obtained by the curette. The very free bleeding was the decisive factor in the choice of a panhysterectomy. There was a fibroid the size of a hazel-nut in the left cornu, and a soft adeno-carcinoma in the right cornu.

Dr DONALD also showed a specimen of carcinoma of the cervix and body of the uterus. The primary growth was evidently in the cervical canal, and the whole cervix above the external os was deeply invaded. Above this, and situated in the muscle of the body of the uterus, was a rounded mass, about the size of a walnut, which proved to be a solid alveolar carcinoma.

PROGNOSIS AND TREATMENT OF ECLAMPSIA AND ALBUMINURIA

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on November 16th, with Dr J S FAIRBANK in the chair, Dr JAMES YOUNG read a paper on the prognosis and treatment of eclampsia and albuminuria, with special reference to the risk of recurrence in subsequent pregnancies.

Dr YOUNG said that investigations during recent years at the Edinburgh Royal Maternity Hospital disproved the usual belief that eclampsia and pre-eclampsia did not tend to recur in succeeding pregnancies. He had previously shown that forty-seven eclamptics had had eclampsia or

albuminuria fifteen times, and abortion, accidental haemorrhage, and stillbirth without toxæmia six times, in their previous gestations, this gave a total recurrence of abnormality of 44.7 per cent. Dr Jessie Sjö, who had followed up forty-two eclamptics who became pregnant again, had found a recurrence of toxæmia in 30 per cent and of total abnormality in 40 per cent of sixty subsequent pregnancies. The recurrence rate in cases of albuminuria and preeclampsia was, in so far as toxæmia was concerned, forty-four in eighty-one, or 54 per cent. Including such conditions as abortion and accidental haemorrhage without toxæmia the recurrence rate was 69 per cent. These figures emphasized the risk of future pregnancies to any patient who had once had a toxæmic pregnancy. Such findings illustrated the inadequacy of the present classification of the toxæmia of late pregnancy, which was based upon the view that the recurrent toxæmia belonged to a class by itself, and was explained as being caused by a chronic renal defect. Dr Young believed that there was no clear evidence that the kidney was ever anything more than a secondary factor. It was often damaged, but this was the result of the action of the toxins, and if long continued was apt to cause persisting renal disease. In two out of sixty-six eclamptics and six out of seventy-three albuminurics, the follow-up revealed evidence of chronic renal disease. The striking fact was that, although the numbers with further toxic pregnancies, and those without, were about equal, in seven out of eight cases with renal defect there had been two or more toxæmic pregnancies. This showed that the chronic kidney lesion was caused by the toxæmia, and was naturally greatest in those most exposed. Such facts indicated the great importance of keeping a patient under strict ante-natal care if she had once had a toxic pregnancy. This need was as nigent in a woman who had had eclampsia as in one with albuminuria. In the present state of knowledge such recurrence could not be prevented in succeeding gestations, and, in view of the high risks, Dr Young suggested, as a working rule, that prevention of pregnancy should be advised where there had been two successive toxic pregnancies. In his experience, when the sequence had once revealed itself in a patient, it usually meant that all the pregnancies would be involved. Except in mild cases it was unwise to allow the pregnancy to continue if the toxæmia appeared before the seventh month. This involved gambling with the life and health of the mother in the interests of the child, whose chances were problematic. It had to be remembered that there was a great risk of the child dying in the uterus as the result of the toxæmia, while many who were born alive survived only for a short time. For these reasons it might be in the interest of the child, as of the mother, in cases seen at a later stage of pregnancy to induce labour at once if the child had reached viability. For the induction of labour Dr Young preferred the use of the gum-elastic bougie, and, as soon as uterine pain commenced, he advised 5-minim doses of pituitary extract, at half-hourly intervals, till a total of 2 ccm had been given. Where the blood pressure was high oxytocin might be preferred. In the comparatively rare cases of severe toxæmia without fits, but in which there was urgency, he preferred Caesarean section under spinal anaesthesia, which was better than general anaesthesia, in that it did not add to the toxæmia. The spinal method eliminated the risk of irritation to the bronchioles and of bronchitis, which was great in such cases, and with it there was a remarkable natural haemostasis of the uterine wound.

The Age Incidence of Carcinoma of the Body of the Uterus

In a joint paper Professors DONALD and FLETCHER SHAW expressed the opinion that, with the rarest exception, cancer of the body of the uterus did not occur under the age of 40, or, alternatively, until after the retrogressive changes of the menopause had commenced. The authors had investigated 177 cases, the scrutiny of which revealed the fact that only one patient was under the age of 40, and even in this instance there was some doubt. In about half the cases the patients were between the ages of 50 and 59, and in one-third between 60 and 69. Definite information as to the onset of the menopause was obtained

in 147 cases, and in only two uncomplicated cases had the disease appeared before the menopause. These results differed considerably from statistics recently published, the difference being mainly in the percentage of cases under the age of 40. Various sources of fallacy were mentioned to account for the discrepancy, these included sarcoma, as distinct from cancer, cervical carcinoma spreading into the body of the uterus, and diagnosis depending solely on the microscopical examination of minute scrapings. The possibility of a causal relationship between uterine fibroids and cancer of the body was mentioned, and also the fact that the retrogressive changes of the menopause might begin at a comparatively early age. In these latter cases the women were sexually older than their years.

Rhabdomyo-sarcoma of the Ovaries

Dr J. D. BURNS and Dr WILFRED SHAW read a short communication on rhabdomyo-sarcoma of the ovaries, occurring in a patient with abdominal enlargement, who was admitted to St Bartholomew's Hospital on June 18th.

She had had two children the last being born two years previously. Menstruation began at the age of 14 and was normal, the last period being just before admission. She was in normal health until three weeks before admission, when she noticed some difficulty in micturition, together with rather rapid enlargement of the abdomen. On examination an elastic tumour was found rising out of the pelvis. It was tender and dull to percussion. On vaginal examination the body of the uterus was found to be not markedly enlarged, the left fornix was depressed by the lower pole of the tumour. The abdomen was opened and the tumour was found to be a cyst of the right ovary. It was not adherent and so was easily removed. There was no ascites or evidence of secondary growths on the peritoneum. The patient made an uninterrupted recovery and was discharged on August 9th. Previous to this she received x-ray treatment over the abdomen, it having been recognized that the tumour was malignant. On microscopical examination the tumour proved to be a rhabdomyo-sarcoma of the ovary.

The Etiology of Cancer

In a short communication on the etiology of cancer Dr R. WISE said that there was abundant evidence that the early cells of the embryo were not always irreversibly determined, there was sometimes a migration of embryonic cells, with subsequent lodgement in various embryonic tissues. These migrated cells, being the original growth cells, were retained for a time, and were nourished in their entirely new and unusual environment. Dr Wise suggested that in cancer cases those migrated embryonic cells, or their descendants, were started in their erratic and uncontrolled multiplication by endocrine stimulation and local irritation.

INDIVIDUALITY AND EPIDEMIC DISEASE

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on November 23rd, with the president, Dr F. E. FREEMANTLE, M.P., in the chair, Dr H. P. NEWSHOLME (Birmingham) read a paper on individuality and epidemic disease.

Dr Newsholme explained that he was taking, in illustration of his theme, outbreaks of disease which were homely in type, rather than widespread epidemics in which individuality might have become submerged. There was a danger, in classifying infectious diseases as separate species, that information arising from individual features in particular outbreaks might be neglected. In one series there were twenty cases of febrile illness in a school, all showing a sudden onset, and consisting of fever, sore throat, and some reddening of the pharynx, not unnaturally the disease was labelled influenza. With one exception the recovery was rapid and uneventful, but the exception was tragic. A convalescent girl became emotional, severe headache developed, and within twenty-four hours there appeared stiffness of the jaw, paralysis of the muscles served by the fifth nerve, salivation, failure of deglutition, and heart weakness, she died a few hours after the onset of the paralysis. At the necropsy no cerebral lesion was evident macroscopically. In childhood she had had considerable nervous tension, had lost a parent when quite young, and had lived a discouraging existence. Thus an outbreak otherwise colourless was brought into prominence by an unusual effect of the disease on one or more individuals. Mostly when this occurred the individuals in

question seemed themselves to have been of exceptional type, suggesting that two factors might be concerned in producing the specific features of a particular outbreak—namely, the stability of the virus, and the qualities of the individual attacked. He gave several instances of this looking upon function as "habit in action," and the functions of the body, of its organs, tissues, cells, as a sort of complex of habits, these habits were capable of being disturbed to the extent of producing loss of function, with the accompanying symptoms. Two factors might bring this about: (1) when the habit was so poorly developed, or so delicately developed, as to need little to upset it, (2) when stress was brought to bear on the habit, this stress being a specific virus or an unfavourable environment, either physical or mental conditions. An interesting confirmation of this difference of manifestation according to the individual was forthcoming in Pugh's experiments on dogs in connexion with acute encephalitis. Some dogs showed the usual symptoms of that disease, while others had symptoms indistinguishable from nervous distemper, these latter being pampered and "spoiled" dogs. In the case of human patients the children forming the exceptions in epidemics were often those whose parents were difficult to handle. A virus which had a relatively slight specificity and comparatively low virulence might cause a general increase in invalidity and mortality by disturbing indiscriminately the cell habits of the most unstable members of the community. Obviously, the more specific the virus, the more easily seen would be its selective action on persons who had a weakness of cell habit: the more virulent the virus, the more readily would it break down cell habits which were even relatively stable. This seemed to be the explanation of the increase in general mortality which was observed during a pre-epidemic period. The increase in specificity which accompanied the course of an outbreak suggested that there might be a reciprocal action between virus and victim. Still, a weakly specific virus would, on the whole, select the person who had corresponding weak cell habits of particular cells: apparently the action of these cells might react on the virus and give it an increased sensitiveness towards cells of the kind. Body cells reacted to a virus by becoming immunized, or specially sensitized against, or rendered specific towards, the virus: the same might reasonably be assumed in reference to the bacterium. Dr. Newsholme quoted Adams to the effect that if man could protect himself against bacteria, bacteria, by increasing their virulence, might guard themselves against extinction by man. In conclusion, the speaker discussed the question of increased specificity with the progress of an epidemic in its bearing on the gradual emergence of more specific types of disease—such as encephalitis or anterior poliomyelitis—out of a wave of infection which was at the outset of a less determinate type.

The President said that this thoughtful paper again drew attention to the importance of soil as well as seed, while stressing the latter.

Sir WILLIAM HAXER related a case in which 20 out of 22 persons assembled at a Christmas party contracted influenza. Their symptoms varied greatly, and as probably most of the persons became infected as the result of meeting on that occasion, one particular bacillary strain being concerned, the variation in the manifestations was an interesting study. The symptoms included mild fever, headache, great gastro-intestinal disturbance, colds, sore throats, and bronchitis. Had these people not been together on that convivial occasion no one would have thought of attributing all those symptoms to a common influenza.

Sir GEORGE BUCHANAN remarked that in the case of such diseases as measles and small-pox the position was governed by the degree of immunity against the disease already possessed, and the question was why when a wave of carrier infection swept through a whole population, the members of a particular household developed symptoms while others went free. The history or the nervous make-up of the persons rendered ill might supply the solution. Sometimes the explanation might prove to be more anatomical than was usually thought—for example, the condition of the nasal and other sinuses might be involved. In the case of post-vaccinal encephalitis some of

these factors could be eliminated. Sometimes a double pathology might be at work.

Surgeon Commander DUDLEY said that the *B. typhosus* could be considered a stable micro-organism, yet in some places typhoid was only a mild disease, while in others it was remarkably virulent, the difference might be accounted for by either racial variants or variants in the organism. He agreed that a double, or a multiple, pathology would sometimes be at work. In swabbing a throat it did not follow that one particular organism detected was the cause of the symptoms, for any of the other varieties seen in the swab might be an important factor. During the war he had been able to trace cases of influenza to particular ships by the character of the chief symptoms. The Pfeiffer bacillus was present in all the cases, but the difference was in the associated organisms. He declared himself a great believer in multiple pathology.

Dr J. A. GLOVER expressed his agreement with the last speaker concerning double infection.

NATURALLY ACQUIRED IMMUNITY

At a meeting of the Liverpool Medical Institution, on November 15th, Dr C. O. STALLIBRASS read a paper illustrated by lantern slides, on naturally acquired immunity in human communities.

Dr Stallibrass outlined the history of our knowledge of acquired immunity, pointing out that knowledge gained from laboratory experiments on animals was not always applicable to man owing to the different portals of infection and the greater longevity of man. The effectiveness of acquired immunity, and the rate at which it was lost in different diseases, could be gauged by the liability to relapses and second attacks. A very high and permanent immunity was often secured in diseases caused by filterable viruses, in the bacterial diseases it tended to be less in the protozoal and spirochetal diseases—for example, relapsing fever and malaria—the immunity was often of a very low order. Much light was thrown upon the rate of loss of immunity in man by the steady increase both in the numbers of lesions and of fatality in severe small-pox with the lapse of time since vaccination was performed. Infection might take the form of the typical clinical cases, the abortive cases—*les formes frustes*—and the subinfections. This latter term was applied by Adams in 1899 to the passage of intestinal organisms, during digestion and in inflammatory states of the intestines, into the lymph channels and the portal system. Each of these types of infection might be effective in producing immunity. The information acquired from tests of susceptibility to toxins (Romer, Schick, Dick) tests of cutaneous hypersensitivity (Zoeller, von Pirquet, typhoidin), and tests for the presence of agglutinins (Vidal, Weil-Felix) had thrown much light on the acquisition of immunity both in the individual and the herd. They indicated a much wider spread of infection or subinfection than was indicated by the statistics of notified diseases. Alongside the visible epidemic of clinically diagnosed cases there was an invisible epidemic of subinfections, revealed only by bacteriological tests or the immune reactions just described, and this invisible epidemic was, in a number of diseases, more effective in the production of herd immunity than was the visible epidemic. Examples were quoted from the typhoid, and more especially the paratyphoid infections, from typhus, from cholera, and from poliomyelitis, in all of which *les formes frustes* and the immunizing subinfections occurred with greater or less frequency. In poliomyelitis there was evidence that a most extensive invisible epidemic accompanied the visible outbreak and left behind it a largely immune population. In other diseases, such as small-pox and measles, the subinfections played little or no part in the production of herd immunity. The converse aspect of the case was the doctrine stated by Dudley that those who had been longest exposed to an infected environment suffered least when exposed to an epidemic, and those who had been least exposed suffered most. Examples were quoted from Dudley relating to typhoid in a warship, and from Evans relating to influenza in the garrison of Woolwich.

Reviews.

THE PRACTICE OF REFRACTION

Among those engaged and interested in ophthalmology Mr W S DUKE-ELDER has already made for himself a considerable reputation by reason of his investigations into the physics and physiology of the conditions that influence the circulation of fluids within the eye, and hence are influential in the causation of glaucoma. Further, his work summarizing recent advances in ophthalmology has marked him out as a keen student and critic of the work of others. He has now produced a book upon a more routine subject, which has been written upon by many workers. It would seem that there could be little new to write about refraction, and little possibility of varying the presentation of the subject. Yet Mr Duke-Elder's *Practice of Refraction*¹ is essentially a new book, and his presentation of the subject is both arresting and illuminative.

At the beginning of the book we are not confronted with the usual diagrams of the paths of light, we are taken right to the heart of human conditions by a thoughtful consideration of evolutionary processes and the important part vision has played in these. Then follows a chapter upon the incidence of eye strain, and the symptoms that are to be associated with refractive errors. These two chapters lift the practice of refraction from the humdrum methods of the so-called "refractionist" to the proper level of intelligent medical practice. They are fitting recognition that the eyes, and their defects and disorders, are intimately associated with the whole make-up of the patient, and cannot be effectively treated without due ability to correlate the general condition of the patient with the condition of the eyes. Mr Duke-Elder, in his consideration of the results of eye strain, makes plain the frequency of ill effects from comparatively small errors of refraction, but he gives a most wholesome and necessary warning against driving this finding to a logical absurdity.

"It should be pointed out that every small error by no means requires correction. There is undoubtedly a tendency at the present time to do this and to provide a large proportion of the population with totally unnecessary glasses. Sometimes this habit is positively pernicious, as in the provision of convex lenses to young hypermetropes with small errors, thereby depriving them of the stimulus to accommodate."

Thereafter the book follows the general lines of such works. But the whole exposition is on a high level, so that it conduces to thought, and not to mere slavish absorption. On one point we could wish the author would reconsider his description of retinoscopy. In the general statement his reference is clearly to the light reflex, but in the account of the variations seen in different forms of refraction he tends to revert to the old custom of description in terms of the shadow. It is true that where there is light there is generally some shadow. The artist gets his effects by deft delineation of the shadows, but the observer finds his delight in recognition of the high lights in the picture. It is certain that students of retinoscopy who learn to look for the movement of the light in the reflex gain a greater mastery of the method, and become much more accurate in their work, than do those who follow the older method of looking upon retinoscopy as the "shadow test" or "skioscopy." The concluding chapter deals with a matter upon which both the ophthalmic surgeon and the general practitioner who does eye work should be informed—the making and fitting of spectacles. Much judgement is needed to determine what form the prescription of glasses should take, and this is to be related as a rule to the type of work that the wearer of the glasses will be engaged in most frequently.

¹ *The Practice of Refraction*. By W Stewart Duke-Elder M.D. F.R.C.S. Churchill's Empire Series. London J and A. Churchill, 1928 (5½ x 8 pp xiii + 410 208 figures, 12s 6d net).

MODERN THERAPEUTICS

Modern Methods of Treatment,² by Dr LOGAN CLENDENING of the University of Kansas, first appeared in 1924, and a second edition has now been published. The chief aim of the author has been to improve the teaching of therapeutics, for his remarks in his preface that instruction given in this subject by teachers of clinical medicine is inadequate, it should be an essential part of the training of all medical students. He also points out some of the chief defects in the existing textbooks of therapeutics. As one of these he mentions a style of deadly boredom—a defect of which he himself cannot be accused, for his book is written in an interesting and sometimes racy manner.

The first part contains 480 pages, and is devoted to general therapeutics, the second, of 300 pages, deals with the application of remedies to particular diseases. In his review of general therapeutics the author has made a careful selection, he discusses the actions of only the more important drugs, and more than half of this part is devoted to dietetics, hydrotherapy, massage, radiotherapy, climatology, and psychotherapy. These important subjects are very difficult to take up systematically in a manual of therapeutics, for one reason because of the dearth of accurate knowledge concerning the effects produced by therapeutic measures other than drugs, and Dr Clendenning deserves praise for his endeavour to provide an adequate discussion of matters usually dismissed in summary fashion by the compilers of textbooks.

The particular merit of this volume is that the author has throughout kept in mind the golden rule that it is patients and not diseases that require treatment. Hence all measures that may benefit a sick person are given due consideration. His style, as we have said, is clear and readable, and important therapeutic principles are frequently driven home by apposite anecdotes from real life. The book is one that can be recommended to the medical profession with confidence, for it is based on sound general principles, it provides well balanced judgements on the relative values of methods of treatment, and it is full of practical hints drawn from personal experience.

X RAYS IN DIAGNOSIS AND TREATMENT

With the improvement of technique in radiological diagnosis, and the extension of radiotherapy, new editions of many of the older useful and popular German treatises have become necessary.

Among recent issues attention may be called to the fifth edition of the *X-ray atlas of the normal in man*³ by Professor RUDOLF GRASHEY of Munich. The fourth edition was reviewed in our columns on March 8th, 1924 (p. 430). Textual changes have been made in the new volume to bring the information up to date, and more illustrations have been incorporated. Special care is taken to indicate how to obtain the best photographs of different parts of the skeleton, and the interpretation of the various normal and abnormal appearances is discussed in a lucid and practical way. Since accuracy in diagnosis depends essentially on appreciating departures from the normal which are sometimes very slight, this book can be commended to students of radiology as likely to help them to determine the standards which must form the basis of judgement.

Professor HERBERT ASHMANN's textbook of radiological diagnosis⁴ has passed into a fourth edition, and we have received the first part of this, which deals mainly with diseases of the heart and lungs. A second part in course of preparation will comprise pathological conditions of the abdominal contents and of the nervous system. Great care has been taken with the illustrations, which are very numerous and include contrasting views of the normal and diseased organs. Recent advances in knowledge are well

² *Modern Methods of Treatment*. By Logan Clendenning, M.D. Second edition. London H. Kimpton 1928 (Roy. 8vo pp. 815 5s 6d figure 45s net).

³ *Atlas typischer Röntgenbilder vom normalen Menschen*. Von Dr med. Rudolf Grashey. Fünfte verbesserte Auflage. Lehmanns Medizintechnik. Allentien Band V. München J. F. Lehmann 1928 (Cr. 4to pp. xi + 226 234 figures on plates and 373 figures in the text M.26).

⁴ *Die klinische Röntgendiagnostik*. Von Dr. Herbert Ashmann. Vierte umgearbeitete und verbesserte Auflage. 1. Hälfte. Leipzig F. C. W. Vogel 1928 (7½ x 10½ pp. 512 1 000 figures, 20 plates M.25).

represented, and the popularity of this useful book should increase.

An attempt to combine radio-diagnosis and therapy in one volume⁵ is made by G. KOMMANN of Oldenburg, who has collected articles on various aspects by a large number of German experts. A wide field of study is thus covered, and some of the articles are of considerable interest, but with so ambitious an objective it is inevitable that there should be a little overlapping and a certain amount of rather dull writing. The index will, however, facilitate reference to special points.

Professor P. KNUSS, on the other hand, finds radio-therapy a sufficiently large subject to justify the publication of a volume⁶ as the third (and last) of a series of books devoted to the application of electricity to medicine. Different authors discuss the treatment of diseases of the eyes, the nervous system, endocrine disorders, and morbid conditions of the thoracic and abdominal contents. Practical details receive full consideration, and clinical cases are described with the aid of illustrations. Numerous references to the German literature on the subject appear at the end of the various sections.

It is convenient to notice here, in conclusion, a handy book⁷ relating to new knowledge regarding the application of electricity to diagnosis and treatment, although radio-logy is expressly excluded from its scope. Professors LUDWIG MANN of Breslau and FRANZ KRAMER of Berlin deal more particularly with the theoretical and scientific sides of their subject, but the various clinical applications receive attention. References to the current literature of various countries are numerous, and the book should be of considerable assistance to those whose interests lie primarily in this branch of research.

MONGOLISM

THE problem of Mongolism has attracted the attention of many investigators probably because it is such a definite distinctive disorder with varied and fascinating aspects for study. Dr KATE BROUSSEAU and Dr H. G. BRAINERD have between them produced the latest contribution on this subject in a monograph entitled *Mongolism: A Study of the Physical and Mental Characteristics of Mongolian Imbeciles*.⁸ While both these authors have had wide experience with Mongols they have refrained from elaborating any new thesis, and instead have brought together and compared the observations and theories of many workers in this field. The result is a valuable and concise exposition of most of the known facts about Mongolian idioct. After a brief introduction the various theories as to etiology are brought forward, and at the end of an otherwise very fair discussion the authors rather lamely support the theory of endocrine disturbance. The next two chapters form the bulk of the book, and contain almost all that is known about the pathology and the physical, nervous, and mental characteristics of Mongolism. A chapter on diagnosis follows, but appears to make differential diagnosis more difficult than it really is. Prognosis is dealt with, and then a very excellent section on therapy and educational training. This last contains many valuable hints for the guidance of those who have to advise about or train Mongol children. But the recommendation for early institutional care in almost every case requires more qualification than is given here, and there might perhaps have been some discussion of "Mongoloid" conditions, some of the very few borderline cases. The lists given of complications and conditions sometimes associated with Mongolism appear to be very full. Congenital obliteration of the bile ducts might be added to the latter, and curiously enough, there

is no mention of the excessive furrowing of the skin of the palms and soles, which is supposed by some observers to be a constant feature of the disorder. The references throughout appear to be very extensive, and these are grouped in a bibliography of nearly twenty pages. The book is altogether a very serviceable summary of present knowledge on the subject.

SOME TEXTBOOKS ON PHYSIOLOGY AND BIOCHEMISTRY

THE serial publication of Dr OTTO FURTH's comprehensive textbook of physiological and pathological chemistry⁹ has received repeated notice in these columns. The edifice continues to grow towards completion with commendable regularity. The sixth part—completing volume 11, and the survivor of the field of metabolism—is now in print. This part is devoted to the problems of the metabolism of fat, nutrition, biological oxidation, gaseous metabolism, and the question of fever. The ground covered is wide, a great body of experimental inquiry is assembled and analysed with a pleasing critical sense. All that is done is well done, and the author shows no sign of wearing of his long and arduous task. The completed work will form a big contribution to the general literature of biochemistry. It is a pity that a careless error in assembly should permit the cover to display a description of the contents which is contradicted by the subject-matter of the part.

The teacher of experimental physiology does not lack a choice of excellent textbooks to assist him in his practical training of students. To add to their number would, therefore, seem justified only if the intention were to challenge conventional methods of instruction. In his *Manual of Experimental Physiology*¹⁰ Dr M. HAMMOUNA expressly disavows this intention. He offers, merely, to a larger public the course which he has found useful to his own classes in the Cairo Medical School. The book follows closely upon the matter and method of its elders. Nevertheless, it has some claims on the attention of teachers and students, particularly those who may be similarly placed to the author and his pupils. Dr Hammouna realizes the width of the preliminary training which is expected of students of physiology in British schools, and feels the disadvantage under which his classes labour. He therefore attempts to smooth the difficulties of those called upon to exploit unfamiliar apparatus and principles—biological, chemical, and electrical—by more detailed descriptions than are usually to be found in such books. It is probable that this manual will be found acceptable to other classes than those of the author.

Elementary Anatomy and Physiology,¹¹ by Dr MARY R. MULLINER, a second edition of which has now appeared, is an interesting textbook addressed to students in hygiene and physical education. In this matter of the general instruction of the laity in the ways of their own bodies there is likely to be a diversity of opinion. Accordingly the form and substance of any particular attempt to provide such instruction is certain to encounter a variety of criticism. The present volume is not above reproach, but, in so far as it represents a serious and painstaking attempt to give an elementary and balanced introduction to human anatomy and physiology, it merits commendation.

ANNALS OF MEDICAL HISTORY

THE third quarterly instalment of the tenth volume of *The Annals of Medical History*,¹² so successfully edited by Dr FRANCIS R. PACKARD, contains twelve articles in addition to the editorial and the book reviews. In his account

⁵ *Kurzes Handbuch der Gesamten Röntgen Diagnostik und Therapie*. Herausgegeben von Gerd Kohlmann. Berlin: S. Karger, 1928. (Sup. roy. 8vo. pp. xi + 917. 773 figures. 8 plates. M.53.)

⁶ *Handbuch der Röntgentherapie*. Herausgegeben von Ges. Medizinalrat Professor Dr. med. Paul Krause. III. Teilband. Leipzig: G. Thieme, 1928. (Sup. roy. 8vo. pp. xv + 731. 273 figures. M.56.)

⁷ *Neuere Erfahrungen auf dem Gebiet der medizinischen Elektrizität, Lehre mit Ausschluss der Röntgenstrahlung*. Herausgegeben von Professor Dr. med. Ludwig Mann unter Mitwirkung von Professor Dr. med. Franz Kramer. Leipzig: G. Thieme, 1928. (Sup. roy. 8vo. pp. vv + 501. 256 figures. M.39.)

⁸ *Mongolism: A Study of the Physical and Mental Characteristics of Mongolian Imbeciles*. By Kate Brousseau, Docteur de l'Université de Paris. Revised by H. G. Brainerd, M.D. London: Baillière Tindall and Cox, Baltimore. The Williams and Wilkins Company, 1928. (Med. 8vo. pp. vii + 210. 37 figures. 20s. net.)

⁹ *Lehrbuch der Physiologischen und Pathologischen Chemie*. Von Dr. Otto Fürth. Band II. Lieferung VI. Leipzig: F. C. W. Vogel, 1928. (Sup. roy. 8vo. pp. vi + 335-615. M.15.)

¹⁰ *A Manual of Experimental Physiology*. By M. Hammouna. Cairo: Whitehead Morris Ltd. 1927. (6 x 9½. pp. xvi + 167. 146 figures.)

¹¹ *Elementary Anatomy and Physiology*. By Mary R. Mulliner. M.D. Second edition, thoroughly revised. The Physical Education Series. London: H. Kimpton, 1928. (6 x 9½. pp. xvi + 403. 309 figures. 2s. net.)

¹² *Annals of Medical History*. Vol. X, No. 3, September 1928. Edited by Francis R. Packard, M.D. New York: Paul H. Hoeber, Inc. London: Baillière Tindall and Cox, 1928. (8½ x 12½. pp. 213-322. Illustrated. Subscription in Great Britain £2 2s. a volume of four numbers.)

of William Heberden's "Prefatory essay to an introduction to the study of physic" Dr Le Roy Crammer describes his discovery and purchase of this unpublished criticism of medical education, and gives a sympathetic review of the life of the author of the *Communicaries*, whose portrait appears on the cover. The frontispiece presents Olof Rudbeck the elder (1630-1702) of Upsala, who is shown by Dr O Larsell to have discovered the lymphatics about 1650 independently of Pecquet. Dr M W Hollingsworth gives an English rendering, apparently for the first time, of Richard Lower's account of blood transfusion in his *Tractatus de Cordis*, the Latin original and the translation being placed side by side. The influence of James Blundell of Guy's Hospital on the development of blood transfusion is described by Drs H D W Jones and G Mackmull, who mention that his removal of a cancerous uterus vaginally was possibly the first operation of its kind in Great Britain. Dr John Rutty of Dublin (1698-1775), a Quaker and friend of John Wesley, took forty years in writing his *Materia Medica, Antiqua et Nova*, and was, as Dr W T S Sharpless shows, very sober on his own shortcomings in the "Spiritual diary and soliloquies," which he kept from 1753 to the year of his death. In "The heritage of Paracelsus" Dr Percy M Dawson of Madison, Wisconsin, contributes, as a supplement to a former article, the considered criticism of one "who opened for himself and other children of mediocrity the door of the future." The life of Theodor Billroth (1829-94), who made Vienna a surgical Mecca and at first operated upon every form of malignant disease, because surgical prognosis was but imperfectly formulated, is detailed by Dr E R Wieso of Pittsburg. The protocol of a necropsy by Bernard Tormus in the fifteenth century is translated from a manuscript in the Riccardian Library at Florence by Dr Lynn Thorndike, who adds some reflections on a record which transports us "as by some magic carpet back into the very midst of the medical theory and practice of long ago." Dr G A Williams contributes a short essay on Michael Servetus, physician and heretic, Dr Andreas Nell of Kandy, Ceylon, writes on the Sinhalese Olas or book manuscripts about early medicines and how they were made, and Dr R L Moodie gives a short note on the palaeopathology of Patagonia. Dr W B Howell of Montreal records how an anaesthetist during the course of a three hours' abdominal operation saw Abernethy, Astley Cooper, and Liston walk into the operating theatre and discuss the strange proceedings, until a nurse tactfully woke him up. Dr Packard (whose name in the table of contents appears on one occasion as "Packad") reviews Dr A G Gibson's book on the Radcliffe Infirmary, Oxford, Dr W C Alvarez of the Mayo Clinic pays a tribute to the wide activities of Dr Nicolas Leon, and Dr Thomas McCrae discusses Professor Hans Kohn's article on the history of angina pectoris.

NOTES ON BOOKS

*The Text book of Histology*¹³ by F T LEWIS and J L BREMER, has an interesting, genealogy. Its immediate fore-runner was the second edition of Lewis and Stohr's *Text-book of Histology*, a book based on the fifteenth German edition of Stohr's histology. The break in continuity with Professor Stohr's textbook took place apparently on account of the incorporation of an embryological introduction to each section, an addition that was unwelcome to Professor Stohr, and the numerous German editions of his textbook, continued after his death, follow the more usual lines in dealing simply with adult tissues and organs. The special feature of the present book is the arrangement on an embryological basis, each section being preceded by several paragraphs giving the developmental history of the organ to be studied. The book is lavishly illustrated with 485 illustrations, of which 32 are in colour.

Most of the candidates for the diploma in public health will welcome the issue of another edition (the tenth) of Dr R BURNETT HAM'S well known *Handbook of Sanitary Law*,¹⁴

¹³ *A Text book of Histology*. By Dr Frederic T Lewis and Dr J L Bremer. Philadelphia: P. Blakiston and Co. London: H. K. Lewis and Co., Ltd. 1928. (Med. 8vo pp. ix + 551. 485 figures. 5 dollars.)
¹⁴ *Handbook of Sanitary Law*. By R. Burnett Ham, M.D. D.P.H. Tenth edition. London: H. K. Lewis and Co., Ltd. 1928. (Fcap 8vo pp. xxxii + 284. 6s 6d net.)

which, since its first issue in 1899, has been largely instrumental in making the study of this subject possible to many candidates, few of whom have had the advantage of a legal training. With this guidance the student is enabled to obtain rapidly a comprehensive view of the extent of the legislation on the various matters dealt with, the handy size of the volume makes it convenient for study at odd moments, an advantage all the greater in that sanitary law is a subject which most people can only absorb in small doses. A useful note is given of the old Acts repealed (and omitted) and the new Acts inserted—a very comprehensive list, the latest item of which is the Nursing Homes Registration Act, 1927. The issue of the book in an interleaved form might be useful to the student, it would certainly be useful to the public health official.

In India, owing to the less advanced state of public health work, medical officers may be called upon to initiate a chemical laboratory and to train and supervise assistants. To help them Lieut Colonel A D STEWART and Major T CRAWFORD BOYD have compiled a manual of *Public Health Laboratory Practice*,¹⁵ which should prove of much service to those whose duties entail the chemical analysis of water, sewage, foodstuffs, etc. The authors give a concise and clear description of the methods of analysis they have found suitable in Bengal and Calcutta. The especial value of this book lies in its application to Indian conditions, as it gives much useful information on the analysis of Indian foods and Indian water supplies. Information is included on food standards, these should be of assistance to local authorities there. The authors have succeeded in embodying in a small compass much practical information relating to the more important parts of public health chemistry.

In their little work on endemic summer typhus¹⁶ Drs D OLMER and JEAN OLMER describe the clinical picture and laboratory findings, with the histories of sixty-two cases, in an outbreak of an eruptive fever which was first observed by one of them in 1922, and since then by many other French practitioners on the Riviera. The eruptive fever is questioned, outbreaks of which have been occurring in the region of Marseilles and on the Mediterranean coast during the hot season of recent years, is probably a modified form of typhus fever akin to Brill's disease or tropical typhus. It differs from the typical, or Old World, typhus in the season of its appearance, its generally mild character, the absence of lice, lack of contagiousness, and low mortality. Inoculation of guinea pigs with the patient's blood did not produce a characteristic rise of temperature, but the Weil-Felix reaction proved positive in a certain number of cases.

¹⁵ *Public Health Laboratory Practice*. By A D Stewart, M.B. F.R.C.S. Ed. D.P.H. and T Crawford Boyd, F.R.C.S.I. D.P.H. London: Milford, Oxford University Press. 1928. (Demy 8vo, pp. iii + 303 + v. 12s 6d net.)

PREPARATIONS AND APPLIANCES

PREPARATIONS FOR TREATMENT OF GLAUCOMA

We have received three preparations sold by the Saccharin Corporation Ltd for the treatment of glaucoma.

Laevo-glucosane contains laevo-rotatory synthetic daltanephren substance which has the same pharmacological action and potency as adrenaline, it also contains 2 per cent of optically inactive methyl-amino-aceto-pyrocatechol substance which is described by Fraenkel (*Arzneimittelsynthese* third edition, p. 442) under the name adrenalon. This is a sympathicomimetic amine which has an action similar to but weaker than adrenaline. This mixture which has a powerful action is intended for instillation into the eye and it is not suitable for sub-conjunctival injection. As it causes moderate burning in the conjunctiva the makers advise preliminary administration of a local anaesthetic (holocaine).

Dextro-glucosane consists of 0.2 per cent of dextro-rotatory daltanephren which corresponds to dextro-rotatory adrenaline and also 1 per cent of methyl-amino-aceto-pyrocatechol. This preparation has an action similar qualitatively to that of laevo-

a totally different preparation for it is 10 per cent) of the amine histamine.

This substance has an exceptionally strong hyperaemia of the conjunctiva and

constriction of the pupil. This preparation is recommended for acute glaucoma.

The use of these preparations is based on the work of Dr Hamburger (*Archives of Ophthalmology*, 1, 533, 1926) who claims that instillation or injection of adrenaline or of amines with a similar action will reduce intraocular pressure in cases of chronic glaucoma by causing constriction of the intraocular vessels. He also claims that histamine reduces the intraocular pressure in acute primary glaucoma. The Saccharin Corporation supply histamine which indicates that Hamburger's claims have been confirmed by various ophthalmologists. If the claims outlined above find general support then these preparations will represent an important advance in the treatment of glaucoma.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

PROGRESS OF THE NEW ORGANIZATION

The annual meeting of the Court of Governors of the London School of Hygiene and Tropical Medicine was held on November 30th in the Council Room of the British Medical Association's House in Tavistock Square, with Sir Holburt Waring in the chair, when the board of management presented the fourth annual report.

It was stated that substantial progress had been made towards the completion of the organization of the school, of the building and of its equipment. The work of the old School of Tropical Medicine, which was taken over in 1924, continues to make satisfactory progress, and the director reported that there was an increase of no less than 17 per cent in the proportion of students sitting for the Diploma in Tropical Medicine and Hygiene who were successful. In the advanced courses in bacteriology established in temporary quarters in Gordon Square, all the five students who sat for the new university diploma were successful in obtaining it.

The project for a new imperial hospital for tropical diseases remains in abeyance in consequence of an important decision taken by the Seamen's Hospital Society, whose representatives have informed the Minister of Health that they no longer intend to close the hospital at Endsleigh Gardens and that it is desired to co-operate very closely with the school and to afford not only the present, but considerably improved facilities for the clinical and pathological study of tropical diseases. The director expressed once more his sense of the debt which the school owes to the society. He referred also to the wide programme of research upon which members of the staff of the school are engaged. The board is applying a part of the capital, as well as the income of the Milner Research Fund to expenditure on research, being fully alive to the importance of the part which research must assume in the work of the school. The term of the agreement with the Government of Southern Rhodesia for the maintenance of a field research station at Salisbury has been extended for a period of five years from February 22nd, 1928.

A school council, it was reported, has been constituted on an academic basis and plays an increasingly important part in the organization of the teaching and research in the school and all associated questions. The board has expressed its intention to recognize to the full the important functions of the council as an expert advisory body and to give effect to its recommendations so far as these are not inconsistent with the board's decisions on those broad questions of policy, administration, and finance for which it is ultimately responsible.

Written representations were made by the board of management to the Minister of Health and through him to the Treasury so long ago as January, 1925 that the original undertaking on the part of the Government to provide the school with a grant of £25,000 a year would be quite inadequate if the school were to proceed with the building which had been planned, with its equipment and with the appointment of the necessary staff. The board pointed out at that time that on the best estimates which could be furnished, an amount of £50,000 per annum would

be required for maintenance, and in submitting estimates for the year 1928-29 it was stated that, upon the closer review of the estimated expenditure now possible, the board did not feel justified in modifying the original figure.

In the new university quarter of London the scheme for a great school of preventive medicine, which is at once a school of the University and an imperial and international centre, is nearing completion. In the ranks of the research workers and post graduate students who will attend this centre there will be found those destined to become the medical officers of health of the future and to serve in this capacity in this country or overseas. The wonderful progress in public health in all directions during the last half century and the rapid growth of an enlightened public opinion which has made this progress possible, give every promise that the new school will succeed and the measure of its success should be reflected in the vital statistics and the reports of medical officers in the future.

The London School of Hygiene and Tropical Medicine owes its inception to the recommendations of a committee presided over by the Earl of Athlone in 1921 and to the timely and large beneficence of the trustees of the Rockefeller Foundation, who recognizing the unique claim of London to be a world centre for the teaching of hygiene, offered the sum of nearly half a million sterling to provide a site and to build and equip a school of hygiene if the British Government would under-

take that it should be adequately maintained. The gift was accepted and the responsibility undertaken. It will be remembered that the old London School of Tropical Medicine at Endsleigh Gardens whose godfather was Joseph Chamberlain and whose first inspired director and guardian for many years was the late Sir Patrick Manson became merged in 1924 under the terms of the Charter and with the cordial support of the managers, the Seamen's Hospital Society in the new corporation. The liaison between the school and the Seamen's Hospital Society—in the provision by the society and its medical staff of clinical and pathological demonstrations—will continue.

The name of the director of the school

Dr. Andrew Balfour is a household word in the tropics as also in their respective spheres of science and medicine are those of the learned professors who are either already actively engaged in teaching and research on the staff of the new school or helping to build up its organization and equipment until the time has arrived next year for them to take charge of their several departments. Professor R. T. Leiper is head of the division of medical zoology which embraces a large part of the subjects taught in the old School of Tropical Medicine. Professor W. W. C. Topley conducts research in bacteriology and the classes for the new university diploma in that branch of science at temporary premises in Gordon Square. Professor M. Greenwood gives special courses in epidemiology and vital statistics at Mount Vernon and has not severed his relations with the Ministry of Health and the Medical Research Council. To the chairs of biochemistry and of chemistry as applied to hygiene have been appointed Professor P. Hartley and Professor M. E. Delafield. Dr. W. W. Jameson has been designated professor of public health and enters upon the charge of this important department of the school's activities in January next.

The new building of which a photograph is reproduced is so far as the main structure goes approaching completion, but will not be ready for the formal opening until the summer of next year. It will be seen to be a noteworthy addition to the public buildings of the metropolis and in its dignified lines and proportions it is a worthy embodiment of the high purposes to which, by the terms of the gift to the British Government, it is to be devoted. The architects—Mr. Morley Horder and Mr. Verner Rees—have made the best possible use of the site which is an excellent one. The building stands behind the British Museum and is near the University College and immediately adjacent to the newly acquired site of the University of London.

NEW LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

The fine lecture theatre will hold about 260 persons. There will be a first class museum running the whole length of the wide frontage, on the second and third floors, and on the semi-basement. The library, occupying the whole length of the Keppel Street frontage on the first floor, whilst fulfilling in its design its primary functions, will also be a handsome reception room for the various social and scientific functions that will take place from time to time in connexion with hygiene and tropical research. In the elevations the architects have achieved largeness, breadth, and solidity. The Keppel Street facade—the frontispiece to the whole building—has been enriched by a deep frieze composed of wreaths, with the names of many great pioneers in hygiene and tropical medicine, as a homage to their work. Finally, efficiency for its purpose as a workshop has been the criterion in the design of every feature of the building.

FARADAY'S DIARY

SIR WILLIAM BRAGG'S DAVID LLOYD ROBERTS LECTURE

THE David Lloyd Roberts Lecture was delivered at the House of the Royal Society of Medicine on November 29th by Sir William Bragg, President of the British Association, whose subject was Faraday's diary. The lecture was preceded by a largely attended reception, at which Lord and Lady Dawson of Penruddock received the guests. An exhibition of some Faraday relics was arranged in the library.

Lord Dawson, in introducing the lecturer, said that this annual lecture had been rendered possible by the generosity and foresight of a distinguished member of the medical profession, Dr. Lloyd Roberts. It was given under the auspices of three different bodies in turn, and this year it had come round to the Royal Society of Medicine. The audience was fortunate in its lecturer, and the lecturer in his subject, for Michael Faraday was a pioneer genius, who had not only added greatly to the knowledge of mankind, but contributed vastly to the civilization we enjoyed. Sir William Bragg was a successor of Faraday as director of the Royal Institution, and possessed in an eminent degree the spirit of his master, alike in searching out the secrets of nature by experiment, in the quality of his thinking, the grace of his diction, and in a certain intangible, but very real, quality of human feeling.

Sir William Bragg said that the work of Faraday had always been to him something to look up to, more particularly since he went to the Royal Institution. Faraday's diary was a day-by-day record, in manuscript, of the researches which he conducted at the Institution from 1828 to 1862. From time to time during the progress of those researches the results were summarized and presented to the Royal Society. The diary possessed an extraordinary fascination for the student of science, and indeed for everyone interested in the development of thought and discovery in Faraday's time. There had been great writers of diaries before, but no one had written a diary of this kind. The diary was interesting first because of the tremendous consequences of Faraday's work upon modern activity. In a world which was drawn together by means of communications based upon Faraday's discoveries, which had learnt from him how to use electricity as a tool, which founded great industries on his laws of electro-chemistry, and had based its conceptions of Nature's forces upon a unity which he was the first to establish experimentally, the account of his researches must be invaluable. But the diary was no mere record of experimental arrangements and observations. Before he planned an experiment it was Faraday's custom to write down all that he thought he might do and perhaps observe. The course of the work would be altered as he proceeded, but at least he would trim his perception by previous consideration to estimate at its true value that which he was about to see. When the experiment was proceeding he stopped to think, puzzled perhaps by some unexpected development, hindered by some failure or inefficiency of his apparatus, but delighted when he made his point. There was a famous passage in the diary where he related how, having tried hundreds of experiments for a fortnight, he had suddenly succeeded, and the capitalized and underscored "But" which broke the long sequence of failures made the page radiant with the triumph of the patient investigator. It was a memorable result too, for it established for the first time a connexion between magnetism and light, the appreciation

of which was vital to the understanding of those electromagnetic theories on which so much of modern science was built, and from which so many modern industries had sprung.

Faraday, the greatest worker in the realm of physics and chemistry that the world had ever seen, worked with a great purpose—that of proving the unity of Nature. He felt that gravity, electricity, magnetism, chemical action, cohesion, light, and heat were all connected with one another, and that their activities were interchangeable. Some of these connexions he succeeded in proving and describing, some he failed to establish, though he declared his conviction that they existed, in later days other workers, using knowledge he could not possess, and apparatus far more powerful than he was able to command, had verified his belief. It was this singleness of aim which led him directly and naturally to his many discoveries. The simplicity which marked his diary was part of his whole life. "If we owe to Faraday the greater part of all those developments of electricity and magnetism which have made our modern world what it is, perhaps it is not for those that the world owes him the greatest debt—not for his experiments at all, but for the spirit in which he made them."

Sir William Bragg then exhibited through the lantern photographs of pages of the diary. The diary contained a million words, six thousand pages, sixteen or seventeen thousand numbered paragraphs, and the writing was of the fine delicate character belonging to the early Victorian period, very clear in a way, but trying if read continuously. Typewritten copies had now been made, which rendered the task somewhat easier, and it was hoped to publish the diary before long. The lecturer also repeated, with apparatus as nearly as possible similar to that which Faraday himself had used, some of his experiments. He described Faraday's momentous discovery of induced currents, whereby he had subdued the domain of magneto-electricity, and prepared the way for every dynamo and motor now functioning. "Simple as the thing looked, it moved the world," Faraday saw further into the nature of electricity than any man of his day. His conception of an electrified body was not that the electrical charge was a sort of liquid in the stuff of the metal, but that the metal furnished the end points for the electrical force which was in surrounding space. Page after page of the diary was devoted to Faraday's quest for the connexion between magnetism and light. Some of the experiments he recorded were really the basis of the electro-magnetic theory. He was equally determined to find some connexion between gravity and light or heat. Although he was on the right track, he never knew how hopeless it was for him to dream of reaching the goal, for how could he have anticipated Einstein, or have guessed that the light from a star bent through an air? Finally, the lecturer repeated some of Faraday's experiments with ice, showing how two pieces of ice placed in warm water would freeze together, an action which introduced Faraday to the fascinating study of crystal structure and the study of the formation of glaciers and their movement.

Sir William Hale-White, in expressing the thanks of the audience, commented upon the great simplicity of Faraday's character. His type of genius must ever be of interest to followers of a calling which touched his own at many points. In a minor way Faraday had an interest also for the profession, because as a boy he had lived in the heart of what was now medical London, at first in Jacob's Well Mews, a few yards from the House of the Royal Society of Medicine, and later in Weymouth Street. Moreover, one of the most distinguished Fellows of the Society, Dr. Bence Jones, was his great personal friend and biographer. It was noteworthy that the founder of the whole science of electricity was a medical man, William Gilbert, President of the College of Physicians and physician to Queen Elizabeth. It was he who coined the word "electricity," and he was credited with twenty separate discoveries in electricity alone. Faraday, Sir William Hale-White continued, was a great lecturer. Few reputations survived the lecture table, but Faraday's had done so, largely because he had followed his own dictum that no one lecturing must do justice to his subject, please his audience, and satisfy the honour of a philosopher.

SATURDAY, DECEMBER 8TH, 1928.

GASTRIC AND DUODENAL ULCERS

WITH the rise of abdominal surgery and the increased opportunities thus offered for observation of what disease has done and of the results of operative intervention, our knowledge of gastric and duodenal ulceration has been changed out of all recognition. There would appear to be evidence, such as that provided in 1922 by Dr Newton Pitt from *post mortem* material, that fatal ulceration of the stomach and duodenum has become absolutely more frequent, and not only more widely recognized, since 1880. The available data—surgical, statistical, medical, diagnostic, therapeutic, and radiological—have mounted up apace in recent years, and during the past twelve months a large number of papers and several reports of discussions have appeared in our columns and elsewhere. These show a remarkable divergence of views, especially on the important matter of treatment, and in this respect not only the somewhat hackneyed question of the relative efficiency of medical and surgical treatment, but as to what is the most advisable operative procedure. This clash of opinion is wholesome in stimulating further investigation and thoughtful consideration of the complicated problems.

The term 'peptic ulcer' has for a considerable time been applied to ulcers occurring within reach of the acid gastric juice—gastric, duodenal and jejunal, the last being the occasional product of gastro-enterostomy—as it seems clearly established that this one etiological factor is common to them all. Possibly with some despair at their complete explanation, the etiological factors have been somewhat overshadowed in recent discussions by the problem of treatment, and yet a moment's thought must show that the necessary basis for prophylactic and curative treatment is a knowledge of causation. It is true that the responsibility of sepsis and bacterial necrosis of the alimentary mucosa is fully recognized, but attention seems now to be focused on the fully developed disease, except with regard to the acute ulcers.

In his Lloyd Roberts Lecture on "Some problems in gastric surgery," printed at page 1021, Sir Berkeley Mornihan, speaking with authority of thirty years' experience (which he modestly agrees may be defined as 'the fruit of mistakes') points out that no real advance in our knowledge of the etiology, clinical course, or treatment of gastric and duodenal ulcer will be made until these are regarded as distinct conditions with differences more fundamental than those of site. He deprecates the use of the terms 'gastro-duodenal ulceration' and 'pyloric ulcer' and further, laying stress on the pyloric vein as a landmark useful in the distinction of gastric from duodenal ulcers, he finds that chronic gastric ulcers close to the pylorus occurred in only 3 per cent of his 2 000 cases. On the other hand, according to Dr Izod Bennett there is little difference between a duodenal ulcer and a gastric ulcer close to the pylorus, and the relation of the pyloric vein to the pylorus is not constant, and its use as a surface marking misleading; thus a reason emerges for the difference of opinion as to the frequency or rarity of gastric ulcers close to the pylorus.

An accurate estimation of the comparative value of the different methods of treating gastric and duodenal ulcers is surrounded with difficulties, and comparisons based on statistics are not free from fallacies. It may be well, therefore, to see on what aspects there is not any serious divergence of opinion. There appears to be a general agreement in the view that medical treatment, including sufficient rest, proper diet, and elimination of septic foci, should always be tried first; that acute ulcers should not be operated upon; and that gastro-enterostomy is often performed unnecessarily. Dr Arthur Huist¹ recently defended his statement that 'gastro-enterostomy is the commonest gastric disorder to-day,' and that undoing gastro-enterostomies is the commonest gastric operation he recommends. Sir Berkeley Mornihan also deprecates the frequency of unnecessary gastro-enterostomies, some of which are ascribed to the physician's advice, and quotes with approval the title of an article in a foreign journal, "Gastro-enterostomy a disease." The surgical recommendation that medical measures should be tried first appears to be balanced by the conviction that it often fails. Thus the President of the Royal College of Surgeons, who confesses to a 'leaning to medicine rather than to surgery,' states that it is beyond all reckoning more dangerous than surgical treatment. On the other hand, the modified Sippy treatment practised for five years by Professor Hugh MacLean² and his colleagues has given extraordinarily good results and in their hands did not cause any anxiety on account of alkalosis or other untoward conditions, except in the presence of advanced chronic interstitial nephritis. They therefore conclude that in the majority of uncomplicated cases operation is unnecessary. In this connexion the long-continued alkaline treatment has been recommended to prevent relapse. As the medical dictum is so diametrically opposed to his own, Sir Berkeley Mornihan has criticized the premisses on which it is based, and has questioned the extremely rapid healing of a penetrating ulcer, but in this connexion an explanation may perhaps be found in Dr A. I. Barclay's interesting paper printed at page 1026. According to Barclay the term 'penetrating,' though apparently justified by radiographic appearances, may really be suggested by, and due to, a heaping up of swollen mucous membrane, so that what appears to be a deep ulcer may in reality be shallow, and therefore capable of healing much more rapidly than would otherwise seem possible. While there is a general agreement as to the method—namely, the neutralization of acidity—among the advocates of medical treatment, there is much divergence of opinion and practice among the surgical experts. Thus the incidence of jejunal ulcer after gastro-enterostomy for duodenal but not for gastric ulcer (a subject recently treated at length by Hurst and Stewart³) has given rise to measures directed to its prevention, and so rendered the procedure less simple.

The view that these ulcers, especially duodenal (Hurst), but also gastric (G. Draper), depend in greater or less degree on an underlying constitutional make-up or diathesis is a logical argument against any operation save, perhaps, extensive removal of the sites of the ulcers but without entering further on the somewhat academic question of such a drastic operation, which after all, bears rather on the decision whether or not to adopt surgical treatment, a brief reference should be made to partial gastrectomy and duodenectomy as a

¹ Hurst A. F. *Lancet*, 1928, ii, 477.

³ Hurst A. F. and Stewart M. J. *Lancet* 1926, ii, 42, 805.

remedy and as a safeguard against recurrence. Sir Berkeley Moynihan and Mr Flint of Leeds are both content with gastro-enterostomy for duodenal ulcer provided that the ulcer is destroyed, and are opposed to partial duodenectomy or gastrectomy as being more serious and dangerous procedures. Mr C. A. Pannett, on the other hand, writing on debatable aspects of gastro-duodenal ulceration, advocates partial duodenectomy for duodenal ulcer, which he has performed in sixty-one cases. Mr Norman Lake urges that, as the cause of ulceration is the acid secretion of the stomach, the only operation that can remove the liability to recurrence of ulceration and bring about a permanent cure in duodenal ulcer is partial gastrectomy. On these divergent opinions it is difficult, at any rate at present, to form a fair and reliable conclusion.

FITNESS FOR INDUSTRIAL WORK

THE factory system is always presenting fresh, insistent problems for the student. The mediaeval craft guilds which governed industry by rigid rules for at least six centuries, came to an end by reason of the inability of their leaders to look ahead and keep pace with the progress of the times. They served their day and generation well so long as communication between one country and another, and even one town and another, was difficult, but when, with steam and growth of population, communication became easy, the limitation placed on output became intolerable. From what we can see, through the veil of years, of the output dating from that era, the guiding principle of the craftsmen seems to have been to supply not, as now, what the people want, but what they thought the people ought to have. In this they were aided by the absence of competition, in the sense understood to-day. Long as the hours worked may have been, the mediaeval craftsmen enjoyed their work. Their skill, derived from a seven years' apprenticeship in the use of the proper tools, and their knowledge of the quality of the material used, were their great asset and pride. Recreation they indulged in—plenty of it, no doubt, with every saint's day as a holiday—but this they seem to have organized so that almost all shared in it.

No glamour of romance can be conjured up around the industrial revolution which followed on the decay of the craft guilds. While it was in progress perhaps the darkest page in English social history came to be written. Industrial unrest dates from then, and although the grossest abuses in the exploitation of child labour have ceased after a century of factory legislation, it is a question whether the dragon's teeth then sown have not raised a crop of other troubles for missionaries and teachers to cope with. No one needs to be told now that one of the phases through which industry is passing is that of mass production. Aspects of this phenomenon form a good deal of the subject-matter of two little books by the writers most competent to deal with them. Professor T. H. Pear in *Fitness for Work*¹ discusses the problems involved in the capacities, abilities, and skill favouring or hindering fitness, the motives underlying work and play, the part played by intelligence, intellect, and skill, and the differences between them, industry, laziness, and other psychological aspects of work, and the effect of all these on present-day employment and play. Professor E. P. Cathcart, in *The Human Factor in Industry*,²

treats of almost precisely the same subjects in chapters under the headings of physiology, fatigue and monotony, alleviation of fatigue, environmental factors, and industrial personnel.

Professor Pear's book reminds one at times of the sage who, behind his hand at his face, laughs at the many aspects under which skill may be regarded, and asks, 'Is industrial skill worth while?' A whole chapter is devoted to answering this question, which would be preposterous were it not for the abnegation of craft skill in the mass production of to-day. 'Skill may become,' he says, 'one of the gravest problems of our time, for all who work for their living and for some who do not.'

In the arts, including surgery, and in games and sports, we revere the skilled person. But to the question, 'Is skill worth while economically, on a mere balancing of expenses against receipts?' the answer depends upon our judgement of economic tendencies. There is the Ford tendency to simplify operations. This would substitute the use of jigs and gauges for all those processes implied in the activity of the craftsman's eye. Laboratory tests would replace, as far as possible, his judgement of material. All such changes tend towards the elimination of skill.

As a society (if we could act as a society) we can either consume more articles produced without skill, or fewer things but made with much skill—for example, masses of cheap machine-made furniture or a few good pieces. Commercial social pressure is towards the former alternative.

Professor Pear has a pretty wit, and draws his examples and analogies from sports, such as skiing and skating, as well as from industrial work. He professes only to have depicted the situation, and to have drawn some of the features which distinguish the development of modern mass production and its effect on the persons engaged on it. 'Knack,' he likens to a state in which the leisured semibreves and minims give place to tense semiquavers and demisemiquavers: the wide folds in the time fabric ruck into pleats. He tries to be extraordinarily fair to what in relation to modern work, is and is not skill, what is and is not intellect, and to the motives animating work and play. He discusses all this with a wealth of illustration and reference to dozens of books and studies in the subject.

The plight we are in is brought home by the fact that monotonous and repetitive work is almost always preferred to varied work if a penny more can be earned by it. What is to be done to render tolerable this development of modern industry? According to Mr Arthur Pound, modern conditions of industry are such that the best thing to do is to train a youth for the right use of leisure. Professor Cathcart, in a significant passage on the natural rhythm with which each individual ordinarily does his work, or would do it if he were allowed, says that if the belief in the existence of the individual rhythm is correct, then the whole system of workshop organization with distribution of shafting throughout the shop, is fundamentally wrong. Instead of working at his optimum rhythm and rate, the average man has to obey the inexorable rhythm of power-driven machinery, and again, in criticizing (not in any carping spirit) the effort to secure vocational selection, the real fundamental trouble he says, is that we know little or nothing of the evolution of aptitudes as age matures.

The factory system has brought many troubles upon mankind. We are paying to-day a heavy price for the selfishness and lack of vision of early industrialists. Some of the hardships followed inevitably

¹ *Fitness for Work*. By T. H. Pear. M.A. B.Sc. London University of London Press Ltd. 1928. (Cr. 8vo pp. 287 5s net.)

² *The Human Factor in Industry*. By E. P. Cathcart. C.B.E. M.D. F.R.S. London. Oxford University Press. 1928. (Cr. 8vo pp. 105 5s net.)

the change from the domestic to the factory system of industry, "but in a larger measure they were due to the fallacy of regarding the workman solely as an economic unit, and ignoring all other aspects of his life." Evils of long growth cannot be cured in a month or a year, but intelligence and goodwill may, in time, provide remedies for some of the worst symptoms. It is comforting, therefore, to note that the professor of psychology and the professor of physiology are agreed that right lines for the rationalization of industry are being worked out by the Industrial Fatigue Research Board and the National Institute of Psychology.

EVOLUTION OF THE BRITISH RACES

SIR ARTHUR KEITH is a never-failing stimulator of thought, particularly when he links the present with the past in order to elucidate processes of development. It was only to be expected that he would make good use of the opportunity afforded him this year when invited to deliver the Huxley Memorial Lecture before the Royal Anthropological Society. The subject of the evolution of the human races is one which arrests attention inevitably, and in Sir Arthur Keith's hands it gained a new interest on November 27th, when he suggested that the modern discoveries with regard to the endocrine glands threw light on old problems of racial differentiation. When Professor Huxley, in January, 1870, addressed a lay audience on the forefathers and forerunners of the English, he disturbed uncomfortably the *esprit de corps* of the orthodox, who held that the peoples of England, Scotland, Wales, and Ireland were fundamentally different. Huxley suggested that any apparent difference was not one of essential origin, but rather of proportion—the proportion in which the Xanthochroic, or Nordic, element was mixed with the Melanochoic, or Iberian, element. In his peroration he went so far as to assert that the arguments about the difference between Anglo-Saxon and Celt were a mere sham and delusion. Sir Arthur Keith, who yields to none in his devotion to the memory of Huxley, used this pronouncement for a text which introduced a fascinating discourse. He checked the arguments of Huxley in the light of modern ethnological discoveries, and showed how the four primitive types—namely, the Xanthochroid, the Mongoloid, the Negroid, and the Australoid—might have come into existence. He then proceeded to suggest how intermediate or graded types might have been produced, also in part as the result of endocrine modifications. In his inimitable way he touched on racial distribution and evolution, bringing into prominence the conflict between civilization and natural evolution in such widely separated and contrasting localities as the Caucasus in ancient times and in our modern centres of industry. He defined the four nationalities of Great Britain and Ireland as being differentiating races which had still further to travel along this road. Their journey was governed by the co-operation of three agents, which were (1) physiological processes, which regulated the growth of the human body and determined its racial characteristics, (2) an isolating or segregating mechanism, both psychological and physical in nature, which tended to preserve a local people in its purity, and thus permitted physiological processes to work undisturbed through many generations, and (3) a selective mechanism, represented by changing environment and inter-racial competition. Hybridity would, therefore, seem to have played only a subsidiary part in the evolution of races. Sir Arthur Keith did not fail to draw the practical deduction that political problems must be considered from a biological and evolutionary

point of view. The full text of his lecture will be found in the *Journal of the Royal Anthropological Institute* (vol. LVIII).

OPIUM PROBLEMS

At the fifty-third session of the Council of the League of Nations, which assembles on December 10th, there will come under consideration the appointment and powers of the Permanent Central Opium Board to be established in accordance with the provisions of the Geneva Convention of 1925. The Board is to consist of eight persons "who, by their technical competence, impartiality, and disinterestedness, will command general confidence", it is provided, moreover, that its members shall be, "in equitable proportions, persons possessing a knowledge of the drug situation, both in the producing and manufacturing countries on the one hand, and in the consuming countries on the other hand, and connected with such countries." They are to be appointed for five years, and are not to hold "any office which puts them in a position of direct dependence on their Governments." As our readers are aware the United States Government has declined to participate in the appointment of the Board, preferring to co-operate in accordance with the provisions of the Hague Convention of 1912 rather than with those of the Geneva Convention of 1925. The Spanish Government has, it is reported, by royal decrees established a State Narcotic Bureau for the restriction of commerce in certain listed narcotics so as to prevent their use without a proper medical prescription. A virtual State monopoly is thus created, under which notification will be given to the Governments of countries with which Spain places orders for the quantities of the narcotics which will be required for legitimate use. It is thus hoped to assist in checking the present excess of manufacture, which leads to illicit traffic. Smuggled opium in Shanghai has led to a serious *mélée* between the municipal police and the military gendarmerie, in the course of which some 20,000 ounces of contraband opium mysteriously disappeared. It is said that the military authorities in the Shanghai area regard the opium trade as their perquisite, and that opium has been the bone of contention in all the *Tuchuns'* warfare for the possession of Shanghai. Doubtless this illicit traffic in opium in China and the Far East will engage the attention of the recently appointed commission of the League of Nations, and prepare the ground for the conference which is to be held next year on the whole question of opium smoking and the licit and illicit trade associated with it. Interesting light has been thrown on the activities of the Indian Government's opium factory at Ghazipur by a recent answer given in the House of Commons. It appears that during the last four years large quantities of morphine have been manufactured at the Government factory at Ghazipur, and "substantial markets" have been found for the sale thereof outside India. Thus, in 1923-24, 4,050 lb of "crude morphine" were sold for 155,993 rupees, in 1924-25, 2,000 lb for 145,211 rupees, and in 1925-26, 6,099 lb for 224,887 rupees. It is stated that the morphine is made "from waste products and contraband opium." We understand that representations have been made to the Government of India to the effect that contraband opium, when seized, should be destroyed rather than utilized for augmenting the excess of the drug already on the market. A memorandum issued by the non-official Anti Opium Information Bureau at Geneva draws attention to a resolution adopted by a committee of the Reichstag, which is considering the reform of the German penal code. This resolution, passed on October 29th, calls upon the Government to take measures to limit the manufacture of narcotic drugs in Germany to the quantities necessary for medical use in

that country, it was formulated after the receipt of a statement showing a very considerable increase in the number of drug addicts in Germany. The proposal is of special interest owing to the fact that Germany has a considerable export trade in narcotic drugs. In view of this it is doubtful if the committee's suggestion is practicable, while among the effects of its adoption—even if the Government were willing to sacrifice the export trade—would be the deprivation of non-manufacturing countries of a source of legitimate supply. The main significance of the resolution is therefore, perhaps, its recognition of the gravity of the drug addiction problem.

THE GENERAL MEDICAL COUNCIL AND THE PRESS

THE disciplinary cases which came before the General Medical Council at its winter session just concluded were neither numerous nor, save in one instance, of general interest. Two of the cases resulted in protracted inquiries, and in both of them the charge was of such a nature that on the grounds of public decency the Council very properly decided to hear them in private. Hitherto it has been the general rule of the lay press that cases which come before the Council shall be reported only if they result in censure of the practitioner's name from the *Medical Register*. No one seems to know how such a rule or custom arose, it is not observed by the medical journals, and circumstances can readily be imagined in which such a suppression might be very unfortunate. The fact that certain charges are pending against a practitioner is often common talk in his neighbourhood—there are always mischievous tongues to spread and decorate such information—and it might be very desirable to have in the general press the explicit statement that he had been exonerated by the court of professional discipline. In so far, at least, as the Council's decision of "not proven" can ever be an exoneration. But in general the lay press has adhered to its rule, sacrificing in consequence many a good "story" from its point of view. Some newspapers lately, however, have not only transgressed this rule, but have scurried up the Council's disciplinary proceedings with all the devices of sensational journalism. During this recent session one practitioner was accused of having committed adultery with a woman with whom he stood in professional relationship, the Council found that the facts alleged were not proved, but this did not prevent a London newspaper from printing under sensational headlines a descriptive sketch of the proceedings, in which we read of the "clenched hands" and "tired face," and so on, of the respondent. The press is, under a most salutary law, prevented from publishing divorce court proceedings beyond certain narrow limits, and it seems rather hard that because a co-respondent in such proceedings happens to be a medical practitioner his case should receive publicity before a professional tribunal which it could not have received in the divorce court itself. On the other hand it would be, even in some of these cases which involve delicate points of professional responsibility, a loss to the medical profession if the Council conducted its disciplinary business in secret. Cases continually arise which deserve reporting in the fullest detail, not because of any piquant interest they may possess, but because of the guidance they afford in the matter of professional ethics. One of these is reported in the *Supplement* this week—the case of a medical man of high personal standing who received a warning from the Council on account of his association with an institution which it was held had advertised to the lay public certain special treatments. The bare announcement of the decision in such a case would be quite valueless without a narrative of the facts upon which it was based and which were brought out at the hearing.

EYE JAZZ

POPULAR journalism has its advantages for the general public, and it has its disadvantages. A wise editor can influence his readers for their benefit, but a foolish editor may bring them to confusion. In no sphere are these potentialities more likely to be realized than in the publication of notes regarding matters of health and sanitation. Of late there have been signs of better care in the issue of articles dealing with health. We are apt to conclude that the foolish articles will only be seen in flimsy dailies and weeklies, and that the wise ones will always mark the more established and responsible journals. But alas! this is not always so. We have just seen a note entitled "Eye gymnastics," published in a daily newspaper of a great provincial city, so great a city that it might be the metropolis of the country were there no London, and the paper is one that has an international reputation in the political sphere, and has helped to shape history in the past. This great paper has fallen before the craze for the light magazine page, but its light is surely darkness when it advises its readers to discard their useful spectacles for a scheme of eye gymnastics that would be more properly described in the term of our heading. Here is the "scheme."

"The best exercise possibly is one in which both the eyes are screwed up tightly whilst the lungs are filled with breath, releasing the eyes and the breath at the same moment suddenly, then blinking the eyes several times. This brings the blood coursing about the eyes. Another is to look up, down, to one side, to the other side as far as possible in each direction changing about as quickly as possible, and then reversing the order."

Had the editor of this most reputable newspaper mislaid his glasses when he passed this for publication? Does he think that the stretched eyes of the myope can be shortened by such jazz, or the crooked eye of the astigmatic made straight, or the stiff eye of the elderly made limber as in youth? Did he forget that in the county school quite near to his editorial sanctum there were children who, by reason of their knowledge of elementary physiology, would blush to write such stuff? The writer of the paragraph in this newspaper says "Undoubtedly for the young such a cure should certainly be tried before artificial aids are adopted." Nothing more pernicious could have been written. To teach such jazz to a child is calculated to start an angry habit spasm distressing to the holder and a curse to the subject of it. Yet there are misguided folk who are actually subjecting their children to this indignity—and they are inconsistent withal, for at a recent inquiry by an educational authority as to why a certain short-sighted boy was attending school without his glasses, the father stated that he was receiving "special treatment" that made glasses unnecessary, yet the father himself found his own glasses an imperative necessity for his work. Why do not the advocates of these monkey tricks (for such they are, as any visitor to the Zoo can see for himself) work their alleged cures in a field where results would be manifest and incontrovertible? Why do they not try to straighten a tip-tilted nose by the practice of gymnastical wriggling of the nasal musculature, or to resolve the efflorescence of a monstrous "frog-blossom" by digital percussion? We would venture to suggest to editors that in publishing such paragraphs they injure the reputation of their journals for sound sense.

IMPERIAL CANCER RESEARCH FUND

At a meeting of the general committee of the Imperial Cancer Research Fund on November 28th, with the president, the Duke of Bedford, in the chair, the annual report of the director, Dr J. A. Murray, F.R.S., was unanimously adopted, on the motion of Sir Humphry Rolleston, chairman of the executive committee. A summary of this report appeared in our last issue (p. 1017). Sir Humphry Rolleston reviewed the ground covered in the report, and

afterwards called attention to the importance of the work of the Fund in promoting critical investigation of the findings of other workers. He referred particularly to such statements as claimed to have demonstrated the infectivity of cancer, or to have established a direct specific causal relationship between diet and cancer. Assertions of this nature were not merely of theoretical interest, but necessarily aroused the attention of the general public, which was naturally anxious to know how much truth there was in them. The adoption of the report was seconded by Sir D'Arcy Power. Moving a vote of thanks to the chairman and members of the executive committee, the sub-committees, the honorary treasurer, and others who had assisted in the work of the Fund, the president referred to the widespread public interest in cancer and to the amount of attention recently given to the clinical aspects of the disease. The immediate practical developments in the treatment of cancer, he pointed out, could of necessity give but little information on the more fundamental problems of the disease. After emphasising the importance of research, he commented on the financial position of the Fund, and referred specially to the approaching cessation of the liberal grant by Lord Atholstan of £2,000 per annum for ten years, which was completely absorbed by the expenses of the Stroud laboratory. He added that unless they could make up this annual income in some way the expenditure on research work would have to be reduced. He expressed the hope that the munificent contributions of £10,000 and £3,000 received through the good offices of Sir Basil Mathew would be followed by other liberal donations.

DEEP SEA FISH

DR MICHAEL GRABHAM may well be called the Grand Old Man of Madeira, on which subtropical island he has been perhaps the best known and most distinguished figure for so many years. Dr Grabham betook himself to Funchal in 1861, there to become the acknowledged leader of the British community and the trusted adviser of the Portuguese on all sorts of medical and other scientific matters. Not long ago he went on an all-night voyage in a fishing boat to the island of Porto Santo to investigate and substantiate the alleged total absence of dental caries among the inhabitants of that remote islet. He tells his readers, in a paper read at the recent meeting of the British Association in Glasgow, with all the zest for adventure of a youth, how well he fared on that occasion on the flesh of "that enticing creature" the great red scorpion fish, grilled over glowing charcoal, with a sweet potato, and washed down with "coffee" made from roasted barley. Reference to the *pièce de résistance* of this meal brings us to the subject of Dr Grabham's paper, which was "The subtropical deep-sea food fishes of the Madeira district." He writes of these with the knowledge of a naturalist and the enthusiasm of an amateur fisherman who has himself dragged many a great fish from its retreat some two thousand feet or more below the surface. But lest the ardour of the reader and possible disciple should be cooled by the thought of having to haul in the above mentioned length of line with a hundred pound sherry at the end of it, he tells us that owing to the destructive effects of rapidly diminishing pressure, "In the last few hundred feet the monster rises faster than we can pull him in, and shoots out of the water like a cork or an empty bottle, not dead but helpless." This and many other valuable food-fishes and their habits, as far as known, are described by Dr Grabham. Of one of these, the *Ruvettus pretiosus* or oil fish of British ichthyologists, he tells that it acts as a violent and sudden purgative if eaten incautiously. Here surely is an opportunity for some of the eager purveyors of cures for intestinal stasis to add to the list of nostrums

samples of which they press upon the often thankless practitioner. In his brief paper, written at the age of 88, Dr Grabham has certainly succeeded in his avowed aim, "of engaging interest and research rather than to speak in detail of the knowledge already acquired from the abysmal depths of subtropical Madeira."

THE KING'S ILLNESS

DURING the past six or seven days the King's illness has caused great anxiety, and the bulletins issued at frequent intervals by his medical attendants have been followed everywhere with profound concern. It must be apparent to all that His Majesty is fighting an acute infection, and that the strain upon his reserves of strength, and in particular upon his circulation, has been severe and continuous. The essential facts in the statement printed below have been authorized for communication to the medical profession.

Reviewing an illness which has now passed into its third week, the clinical picture becomes more complete.

The lung infection belongs to a type with which clinicians have become acquainted during the last ten years. A variety in which there is no set duration—no crisis—but where there are phases or chapters of infection varying in number, where the temperature settles slowly and intermittently. It is for this reason that the strain on the heart is so considerable, the strain being decided not only by the violence but by the length of the infection. The widespread pleurisy unfortunately extended to the diaphragm, causing severe pain, which needed constant control. Attacks of bronchial spasm have from time to time added to the difficulties.

As early as practicable in the illness a blood culture was taken and a positive result obtained. This infection was coccal in character. Blood counts have shown a leucocytosis of the polymorphonuclear variety. Radiology has been useful, and the clear pictures obtained confirmed the clinical evidence that the lower two-thirds of the right lung was the area involved.

As all physicians know, an important part of the treatment consists in saving the patient the wear and tear of pain and distress, and promoting restfulness and sleep, and in this the best of British nursing is playing no small part. In addition to the foregoing, therapy directed against the infection has taken the form of chemical antidotes, the raising of immunity, and the promotion of leucocytosis. There is reason to think that a measure of control—and it is to be hoped a measure of curtailment—has thus been secured. At this date (Wednesday, December 5th) the physical signs in the chest have diminished and the corresponding local symptoms have improved. There is, however, still ebb and flow. There is up to the present no appreciable pleural effusion.

Medical men do not need to be told that the strain on the myocardium of a severe infection lasting over two weeks must be an anxious problem, and especially in a patient over 60 years of age. This strain on the heart and the severity of the general toxæmia are together the chief cause of the serious anxiety which must for some days continue to exist.

The following have contributed in their various ways to the care of His Majesty during his present illness: Lord Dawson of Penn, Sir Stanley Hewett, Sir Humphry Rolleston, Sir E. Farquhar Buzzard, Dr L. E. H. Whitby, Dr H. K. Graham Hodgson, Nurse Pordie (Westminster Hospital), Nurse Black (London Hospital), Nurse Davies (London Hospital), and Nurse Gordon (St. Thomas's Hospital).

Nova et Vetera.

A CLINICAL NOTEBOOK OF 1710

This small vellum covered book of one hundred pages, measuring six inches by four, with a still efficient metal clasp, is filled with notes of cases taken, as the dates show, in the year 1710. In appearance it much resembles a modern bankers' passbook. It once belonged to Dr Thomas Wallace of Ipswich (1680-1763), and it is to the kindness of his great-great-grandson, Mr W Roco Wallace, that we owe the opportunity of examining it. Oddly enough, the name of Dr Wallace only appears in pencil on the end paper, and here it is hardly in the form of an autograph. The name of John Brownian is written in a contemporary hand in ink on the flyleaf, but the hand differs from that in which the notes are written. Besides notes of hospital cases the book contains five pages headed "Symptomata," which consist of a list of symptoms and names of diseases and of remedies for them. At the end of the book half a dozen reversed pages are devoted to rules and examples of arithmetical progression, a subject which seems to have little enough to do with medicine or therapeutics.

The greater, medical, part is written in a very clear hand and in Latin, and at the top of the page is generally written the name of the ward in which the patient lay. These ward names constitute the chief indication of the place where the observations were made. There are thirteen wards mentioned, as follows: Susannah, Lazarus, Cutting, Isaac, Jacob, Noah, King's, Jennal, Tobias, Job, Lydia, Deicas, Elizabeth. It seemed obvious that in the year 1710, when hardly any provincial hospitals existed and certainly none at Ipswich, these notes could only refer to some hospital in London. Inquiries made and courteously answered by the secretaries of St Bartholomew's and St Thomas's Hospitals showed that of the thirteen ward-names in the book, ten were in use at St Thomas's about the date in question, and the remaining three might have been found to have been in use there had not certain records disappeared. Five of the names were also in use at St Bartholomew's, including the strange one of Cutting, which was common to the two hospitals. Sir D'Arey Power kindly tells us that "The Cutting ward was the operation ward at St Bartholomew's Hospital, and for convenience the deadhouse was just underneath, so it must have been in the Cloisters—i.e., a range of rooms on pillars." In addition to the evidence of the ward names the fact that the names of Drs Mead and Cotesworth are mentioned in the notebook makes it almost certain that the note-taker made his observations on patients in St Thomas's. Of the famous Dr Mead there is no need to say more. Dr Cotesworth was Caleb Cotesworth, M.D., of whom we learn from Munk's Roll of the Royal College of Physicians that he was

'formerly a surgeon but then disfranchised of his company' was on the 1st October 1688, admitted a licentiate. He was created doctor of medicine by Tillolson Archbishop of Canterbury on 3rd March 1692, and was admitted a Fellow of the Royal Society in 1718. He was physician to St Thomas's Hospital, and died on 2nd May, 1741, having amassed a fortune of between one and two hundred thousand pounds the greater part of which he left to his wife, who, surviving him only a few hours, died intestate.

His history is a good instance of the possibility at that time of making a fortune out of physic, without leaving any mark on the progress or history of the medical art. It also furnishes an example of the strictness with which the College of Physicians then, and for a long time, repudiated the taint of surgery. Every surgeon who desired to become a licentiate was obliged, as was Cotesworth, formally to divest himself of all official connexion with the Company of Barber Surgeons or later with the Corporation of Surgeons.

In turning over the leaves of this little book the first thing that strikes us is the absence of all but one reference to surgery, even in Cutting ward. Most of the cases in this ward, however, have no disease recorded against their names, but only prescriptions. The writer may therefore have ignored their surgical aspects. The second is a

similar silence on the subject of bleeding, which does not seem to have come into vogue so early as 1710, and the third is the great frequency with which blisters were ordered. A patient was lucky, apparently, if he or she left hospital without having been blistered several times. Blisters to the nape of the neck were almost as common as a dose of house medicine. We must confess that we are puzzled by some of the abbreviations used. A very common one is "B et C." For instance, in Lazarus ward John Barwell, who was "luc venerat inguinatus," was ordered "B e C h s nq purg p o d 3ss", and again "B e C D D em lacto." We hope that some of our readers more learned in ancient prescriptions may be able to interpret these signs. Lazarus seems to have been a "foul" ward. In it Richard Tomlins, who was afflicted with nudes on the arm, leg, forearm, and wrist, with severe pain (dolore vehementi) of the left arm, was very vigorously treated. He took Bolus 17, vomitus 11, pil 7 (vomitus exhibitum superiore die Secuta est pilula de inferiore oe) et unctione 111. He recovered after remaining in hospital over two months. The record ends "NB Omnia haec per dejectione operabantur." Epileptics were given blisters to the head and haustus epilepticus. After three such prescriptions a note is added "Hi tres Epileptici erant," so that there should be no possibility of mistake. Yet there may have been, for one of the three is stated to have been cured—"Curatus" is the laconic but triumphant note. This case was blistered on the calf instead of the head. Samuel Males, who "gravior epileptici orat," was blistered on the right arm and "nearly all the head," but despite these and other remedies "abut meritis."

The names of patients in this book are those still familiar in English country places to-day. "Sara Mendapace" seems auspicious, but, alas for Sara! the diagnosis was "Uteri Cancer." There is a total absence of "Maes" among these names, and there are very few obviously Irish or Welsh. The Celtic fringe had not yet begun to assert itself.

The pharmacy of this notebook is practically that of Salmond's translation of the *Pharmacopoeia Batava*, second edition, published in 1700—only ten years earlier. This work by Sir George Bate, who was physician to Charles I, Oliver Cromwell, and Charles II, was long popular. Some of the rather disgusting and ineffective animal materia medica survived. Aqua or liquor limacum was made from red snails and salt, and Salmond said it was "a singular noddyne and arthritic." Haustus epilepticus was much prescribed in these notes, but there is no haustus of any sort in Bate. Electuarium epilepticum, however, contained "white dung of a peacock, dried." Spiritus millepedum was made from wood-lice, which Glisson had recommended in the cure of rickets. Salmond said that it "opens all obstructions."

We have only found one record of a surgical operation—a case of lithotomy, which proved fatal.

The touching belief here shown in the efficacy of a whole list of drugs which we know to have had none but a psychological effect, was of long standing in 1710, and still lingers. It will probably be long before "advice and a bottle of medicine" (especially the bottle) ceases to be demanded by millions of our fellow countrymen.

E. MUIRHEAD LITTLE

A REPORT on Borna's disease, prepared by S. Nicolas and J. A. Galloway, and recently published by the Medical Research Council (Special Report Series, No. 121), contains special points of interest to students of human neurology. Although this dangerous communicable disease of horses, cattle, and sheep has not spread to this country from America, it is not unknown in continental Europe. The immediate interest which the pathology of Borna's disease has to medical science depends on the fact that this is a virus disease, and the present report is a useful contribution to our knowledge of virus diseases in general. Moreover, the infective virus produces changes in the brain and spinal cord, the so-called encephalo-mylitis of sheep and cattle, which throw light on analogous forms of encephalitis and myelitis that occur in sporadic or epidemic form in human beings. In addition to gaining new knowledge of the general pathology of this disease, the authors have shown that animals can be successfully immunized against it.

NOISE AND THE PUBLIC HEALTH

DEPUTATION TO MR NEVILLE CHAMBERLAIN

A joint deputation from the British Medical Association and the People's League of Health was received by Mr Neville Chamberlain, M.P., Minister of Health, on December 4th, the purpose of the deputation being to present to the Minister resolutions recently passed by these bodies on the subject of noise in relation to public health.

The representatives of the British Medical Association, who were introduced by Sir Richard Luce, M.P., were Dr H B Brackenbury (Chairman of Council), Dr C O Hawthorne (Chairman of Representative Body), Mr N Bishop Harman (Treasurer), Dr J W Bone (Chairman of Medical-Political Committee), Dr Dan McKenzie, B.M.S., T G Nasmyth (Edinburgh), Dr Alfred Cox (Medical Secretary), and Dr Courtenay Lord (Assistant Medical Secretary).

Sir THOMAS HORDER introduced the People's League of Health deputation, which consisted of Sir Robert Armstrong-Jones, Professor C Robertson (University of Edinburgh), Dr Thomas Beaton (Medical Superintendent, Portsmouth Mental Hospital), Dr M B Ray, Mr E B Turner, and others, with Miss Olga Nethersole (Honorary Organizer of the League).

The Minister was accompanied by Sir George Newman, Senior Medical Officer.

Dr BRACKENBURY explained that at the last Representative Meeting of the British Medical Association a resolution on the subject of noise was carried unanimously. This resolution had a Scottish origin, and, of course, it was recognized that the Ministry of Health had to do administratively with England and Wales, and another body with Scotland, but it was the business of the Council of the British Medical Association to carry into effect, so far as it could, the opinions of the Representative Body, and it had acted upon this resolution in two ways in Great Britain to bring to the notice of their local authorities the need for using whatever powers those authorities might possess with a view to the suppression of unnecessary noises, and, in the second place, it had presented the resolution to the Minister, together with a memorandum dealing with the subject in its clinical and scientific, and not so much in its administrative, aspects. On the medical and scientific side this was regarded as an urgent matter, and his Council was fortified in that view by the very large volume of support which the action of the Association had received, both from the public press, and, through correspondence, from individuals and public or semi-public bodies. The Association had been urged to persevere in this matter to the best of its ability. In addition to such reinforcement some further points had been brought to the knowledge of the Association, such as, in certain localities, the noise of aeroplanes, and, in certain small towns, the noise arising from traffic over cobbled roads. This latter nuisance appeared to be even greater than was supposed when the memorandum was drawn up.

Mr CHAMBERLAIN: Is that a recent development?

Dr BRACKENBURY: It has become more evident to us as a public danger from the correspondence which has followed the publicity given to our resolution. Not only is the motor and other traffic much greater over these cobbled pavements but for protection people are driven to close their windows and thus they suffer again from lack of proper ventilation.

Mr CHAMBERLAIN: They have been doing that for hundreds of years.

Dr BRACKENBURY: At any rate there has not been the same necessity for doing it in the past. We have been trying to teach people the need for domestic ventilation and now this fresh element comes in. I have only to add that we in taking this action are voicing a large volume of professional and public opinion.

Baillie NASMYTH (Edinburgh) said that he had been a medical officer of health for about thirty years, and, of course, he had had continuously to deal with nuisances of various kinds. This very serious nuisance, however, was not dealt with under the Public Health Acts either of Scotland

or England. In 1927 he brought the matter before the Public Health Committee of the Edinburgh Town Council. It was readily taken up, and he was surprised at the prompt acquiescence in his view that noise had become a great nuisance, he was surprised also at the volume of opinion on this subject from the medical profession, culminating in the unanimous passing of the resolution from the Edinburgh Division at the Cardiff meeting in July. The Public Health Committee in Edinburgh unanimously resolved to recommend that suitable provisions on this subject should be inserted in the next provisional order promoted by the corporation, and this course had again been approved unanimously by the Edinburgh authorities. He wished to emphasize the extraordinary support these proposals had received from the press all over the country, an indication that people were becoming seriously alarmed as to the devastating effect of noise on public health.

Dr DAN MCKENZIE wished to emphasize two points. In the first place, as practising physicians and surgeons, their interest in the matter was the interest of the sick person, and from experience in their practices they knew that the public noises in London and other big cities caused much interference with the process of recovery. In the second place, they were mindful of the interests of persons in health, whose exposure to the deleterious effects of noise had also to be considered, because the noises were of such a nature as to interfere with necessary repose. This interference was found to reduce the amount of good work done by the community, though it was difficult to estimate the full extent of the harm thus wrought. He wished to add that it had been shown during the past year or two that it was possible to reduce noises in the streets of London—for example, whistling for taxis—with the minimum of inconvenience. There were a large number of noises of the same character in the streets, and some of them might be eliminated by a little arrangement without disadvantage to anyone.

Sir THOMAS HORDER then introduced the representatives of the People's League of Health. He said that the persistence and increase of noises in and about the streets had become an intolerable nuisance, and likely to cause serious damage to the nervous system. He read a resolution which had been carried at a meeting of the People's League of Health on February 22nd, urging the control and diminution of preventable noises in view of the emphasis by eminent neurologists and mental experts of the grave effect of noise upon the nervous system and its part in increasing the incidence of functional mental and nervous disorders. He also read a letter from Sir Maurice Craig, who was unable to be present, stating that he (Sir Maurice) had been impressed for many years by the increasing number of persons whose health had suffered from noises in the streets of London. Sound sleep being a fundamental necessity for mental health, it was evident how important the question of disturbing noises became. When exposed to such noises the auditory centres in the brain could never be at rest and nerve fatigue resulted, with all its concomitant disabling symptoms. Over-stimulation of the nervous system was one of the most important factors in bringing about minor and at times major mental disorder, and noise was an important cause of such over-stimulation. Sir Thomas Horder read another letter from Sir Thomas Oliver of the University of Durham, who wrote of the ill effects of noise on the health of work-people in factories and other places where this nuisance was really preventable. Some machinery was so deafening as to produce not only temporary but permanent disability. Only a small percentage of men who followed the occupation of riveting for fifteen or twenty years escaped deafness.

Sir ROBERT ARMSTRONG-JONES said that he spoke with some knowledge and authority on behalf of the mentally ill, who frequently also suffered from certain functional nervous disturbances, such as irritability, erethism, exhaustion, and anxiety. To the neurotic person, "who did the work of the world," sleep was a vital necessity, but under present conditions often impossible of attainment. The ordinary worker who had a prearranged setting for his period of rest was repeatedly roused by loud and disturbing noises, and rose in the morning shaky, confused,

and unrefreshed after his so called night's rest. His health suffered in consequence, his work deteriorated, and he joined eventually that highly sensitive neurasthenic group of persons who jumped every time the clock struck. The general health of children also soon became affected, and their growth impeded through lack of sleep. The human ear was a double instrument, not only hearing sounds, but keeping the body balanced and the muscles in proper tension through the vestibular nerve. The effect of noise was therefore not only to disturb rest, but to bring about unsteadiness and giddiness and create muscular tremors. Noises also, or strong arrhythmic vibrations, were as definitely conveyed to the bones of the skull as to the walls of a house, and the fluid which was the essential conductor of sound within the canals of the ears passed on these vibrations to the brain, even subconsciously during sleep, with the result that the sleep was unrefreshing and the fatigue not lessened. The noises that disturbed sleep and distressed the mind comprised the sudden unexpected shocks, such as loud motor hooters, uncontrolled exhausts, pneumatic drills, vibrations of fast-driven vehicles with solid tyres, railway whistles, barking dogs, milk cans, noisy trains and trams, and all kinds of strident horns. He begged that local authorities might be given power to stop hooting and prohibit the use of solid tyres.

Professor GEORGE ROBERTSON (Edinburgh) said that noise was more harmful to the highly strung and nervous, many of whom were the salt of the earth. He called attention to three effects of noise: (1) disturbance, excitation, and irritation, which had consequences of many kinds on conduct, (2) constant strain on nervous energy, causing mental exhaustion and neurasthenia, and (3) broken and interrupted sleep. Loss of sleep occurred as a cause or symptom of mental breakdown in about 75 per cent of cases, and was undoubtedly one of the causes of insanity, even as the production of sleep was one of the means whereby insanity was prevented or cured.

Dr THOMAS BEATON (Portsmouth) drew attention to the great incidence of mental and nervous trouble, and said that noise was evidently a large contributory factor.

Dr M. B. RAY said that perpetual over-stimulation of the auditory sense had a most deleterious effect upon the power of concentration in children and adults, and produced varying degrees of instability. He also spoke of the noises around city hospitals, especially at night.

Mr E. B. TURNER gave his experience of the numerous cases of illness which immediately followed the removal, many years ago, of the bars in the South Paddington residential district, which bars had hitherto prevented the great volume of horsed goods traffic from the Great Western station proceeding at all hours of the day and night through the quiet squares and streets of that district. He suggested legal action to enforce "zones of silence" around hospitals, white lines drawn across openings of side roads into main roads, and a ten miles an hour limit at such points, thus doing away with hooting when vehicles crossed side roads, limitation of weight and bulk of goods carried by road, enforcement of the use of pneumatic tyres on lorries, prevention of sale of motor cycles not efficiently silenced, the making of by-pass roads to cut off as many country and suburban towns as possible, and the amendment of Section 91 of the Public Health Act, 1875, so as to include noise among statutory nuisances.

The Minister's Reply

Mr NEVILLE CHAMBERLAIN, in replying to the discussion, to which, he said, he had listened with much interest, for he, like most other individuals, not only disliked but resented noises, spoke as follows:

When it comes to practical measures to reduce noise, I think you probably realize that this is a matter which is more in the hands of the Minister of Transport and the Home Secretary than in those of the Minister of Health. It is for them to deal with noise as a matter of order and government, and, in fact, they are now considering what further regulations shall be made to reduce preventable noise. It is true that Sir Thomas Horder has just suggested that I should undertake the amendment of the

Public Health Act, 1875, and include noise among the various matters which may be treated as nuisances. It is a fact that the nuisances dealt with under the Public Health Act are confined to sanitary matters, and noise cannot be brought under the statute as it stands, though certainly, assuming all other things were favourable, it would be possible to insert an additional clause to bring in noise. But I think that before such an amendment were introduced the question would have to be considered much more carefully than those who have had it in hand have thought necessary up to the present. It would be necessary to consider, first of all, how to define noises, and, secondly, how to prevent them. It is obvious, for instance, that such noises as the barking of dogs—and, I might add, the caterwauling of cats—which may be very distressing to people, especially at night, are noises which, nevertheless, it would be very difficult to prevent.

What is it, then, that you suggest that I should do as a result of this deputation? I confess I am not quite sure. You desire to impress me with the weight of your opinion as to the injurious effects of noise upon health, and possibly you have it in mind that if I am sufficiently impressed I may add my voice to the representations which have already been addressed to the Home Secretary. You may think that, by making a little noise in his ear and in that of the Minister of Transport, I may induce them to treat this matter with more urgency and in greater completeness ("Hear, hear"). Well, I am not at all indisposed to take a sympathetic view on that point (Applause). But I want to say something further to you—namely, that the impression left upon my mind from what you have said is that every speaker has had in view, not the needs of healthy people, but of sick people. I see some of you shake your heads, but I am going to say something more on that point. I know that you have said in a general way that the nuisance of noise affects healthy people as well as sick, and Sir Robert Armstrong-Jones has drawn a most alarming picture of what may happen to the healthy community if these noises continue. Well, I hope I am a healthy person, but I do not recognize these effects as occurring in my own case. It is true that I am sometimes—not often—kept awake at night, but it is not the noises that keep me awake, it is other matters, such as worry. Although the noises may be startling, unexpected, and arrhythmic, they do not trouble me. No doubt, if I were one of those neurotic people who "do all the work in the world" they would trouble me greatly, but whilst I entirely agree that these neurotic people are made more neurotic by the noises that go on, yet when you have got a person in that condition are you ever going to be able to keep the streets in great cities so quiet that he will sleep peacefully at night and recover his health? Perhaps you can answer that question with more confidence than I can, but it does seem to me that, the fact of these noises being, as it would appear, almost inseparable from our city life, the conclusion to which you might be led would be rather to take your hospitals somewhere else than to try to stop the noises round about them in the places where they stand to-day.

One thing I do feel very strongly, and that is that we still lack precise knowledge upon this subject, and there is a wide scope for further scientific investigation. Take the question which has been touched upon by one speaker to-day—namely, the noise in industrial establishments. One member of the deputation spoke definitely of serious injury being done to health as a result of that noise. But I venture—though not a medical man—to express some doubt as to whether there is at our disposal precise evidence of any such injury occurring in factories to any great extent. I have been in cotton mills in Yorkshire, and to me, who had never been in such places before, the noise was shattering, but I saw people who were working there, and I was told that the output was by no means diminished on account of the fact that the noise was proceeding. In the opinion of many people the human organization adapts itself to conditions which are going on all the time, and very soon—the time is extremely short in some cases—the conditions cease apparently to have any detrimental effect. I only give you that as the sort of opinion I have

heard expressed on the subject, and not as a positive opinion of my own. But surely this whole complicated subject is one which can be investigated. I believe that experiments are already being carried out by the Industrial Fatigue Research Board, which is looking into the effect of noise upon the nervous constitution, among other things.

I put it to you that it is very easy to express opinions which are, *prima facie*, probable about this question of noise, but this is hardly sufficient, and no really requires something much more reliable, founded upon not merely the opinion of this or that person—because all persons may be fallible on these matters, and even doctors sometimes take different points of view—but upon definite scientific measurements and accumulative data, which would enable us to see what is the damage that may be done, what, for example, is the precise form of noise which causes the most damage, and, therefore, what are the points to which we ought most carefully to direct our attention.

That is all, I think, that I want to say to you in reply. I will, however, assure you that the words you have said to me and the various memoranda that you desire to leave with me will be most carefully studied. I have the greatest sympathy with your general purpose, and I desire, wherever it is possible, to see that preventable noises shall be prevented. I shall have much pleasure in telling my right honourable friend the Home Secretary what this very influential and weighty deputation has said before me.

The deputation then withdrew.

THE ROYAL SOCIETY ANNIVERSARY MEETING

THE anniversary meeting of the Royal Society of London was held as usual on St Andrew's Day, November 30th. The president, Sir ERNEST RUTHERFORD, delivered an address on the present state of experimental knowledge with regard to the production of very high frequency radiations of the x-ray type.

PRESIDENT'S ADDRESS

As usual, the president began his address by referring to the Fellows who had died during the previous year.

Sir David Ferrier

OF Sir David Ferrier, who was a vice-president of the Society in 1906-8, and had been a Fellow for fifty-two years at the time of his death, he said:

We have lost a pioneer investigator of the physiology of the brain whose work laid the experimental foundation of all modern knowledge of the localized functions of the cerebral cortex and thereby opened a new epoch in the medical diagnosis of disease or injury of the brain and in their relief by surgical operation. Ferrier was one of the founders of the Physiological and of the Neurological Society and one of the small group who in 1878 started the journal *Brain* to deal with neurology in its widest experimental and clinical aspects. For many years an honoured and successful physician he preserved to an advanced age an enthusiastic interest in the advance of neurology by the experimental method.

Sir Hugh K Anderson

Sir Hugh K Anderson, the president said, had been a Fellow of the Royal Society since 1907, and was a member of the council at the time of his recent death.

Returning to Cambridge in 1891 on the completion of his medical course in London he devoted himself during the next fourteen years with self-sacrificing zeal and conspicuous success to research and teaching in his chosen subject of physiology. He was one of the investigators who were then unravelling the intricacies of the autonomic system and shaping the conceptions of its function now everywhere accepted. The series of classical papers in which he was associated with the late Professor Langley and his later and independent work on the complex reactions of the pupil of the eye had shown him to the world of science as a coming master in his subject while to every Cambridge man who in that period entered upon research or higher study in physiology Anderson had been lavish in his gift of interest, encouragement and personal help. From 1905 onwards the recog-

nition of his aptitude for business drew him, always diffident and reluctant, away from research into the wider affairs of his College and of his University. As a member of the Royal and Statutory Commissions and in many other capacities he did inestimable service to Cambridge to science, and to education, and earned the honour and affection of a wide circle beyond his University and our Society.

Other Deceased Fellows

The president also referred to the deaths of Professor Noel Paton, who was among the first British physiologists to investigate metabolic problems, and had more recently devoted many years of experimental study to the function of the parathyroid glands, of Sir Charles Tomes, the great pioneer in dental anatomy, who might be said to have founded the science of comparative dental histology, and of Professor Hans Gadon, for many years lecturer and reader in the advanced morphology of vertebrates in the University of Cambridge.

David Ferrier Lecture

He announced that a sum of £1,000 had been presented to the Royal Society for the foundation of a lecture in memory of Sir David Ferrier. The intervals at which the David Ferrier Lecture will be given and the subjects with which it will deal will be determined later.

Foulerton Professorships

Sir Ernest Rutherford mentioned that the late Professor Starling had been elected Foulerton professor in 1922, and had been responsible for a distinguished record of research during his tenure of the chair. The council had recently decided to fill this chair by appointing Dr Edgar Douglas Adrian, lecturer in physiology in the University of Cambridge. The president referred to Dr Adrian's distinguished record in the investigation of the physiology of the nervous system, and said that, during recent years, with the aid of apparatus, using the modern means of electrical amplification, he had been engaged in recording and analysing the minute changes which were transmitted from an excited peripheral sense-organ along the conducting system of the nerves, and which resulted in some form of sensation.

The second Foulerton professor, Dr Archibald Vivian Hill, had been appointed in January, 1926 and had since then conducted an important series of investigations on the energy changes and physico-chemical processes involved in the measurable vital activities of muscle and nerve.

He has measured for instance with specially devised apparatus of extreme delicacy the minute quantity of heat liberated in the passage of a wave of excitation along a nerve and also the different factors concerned in the efficient muscular activity of man as exhibited in the running of trained athletes. It is significant of the wide interest in these researches to which his Foulerton professorship has enabled Dr Hill to devote his whole time, that they have been published largely in our own *Proceedings*, under the names of some sixteen investigators who have come to work with him from seven different countries.

ANNUAL DINNER

The 266th annual dinner of the Royal Society was held in the evening at the Hotel Victoria, with Sir ERNEST RUTHERFORD in the chair. Sir SAMUEL HORSER, proposing the toast of "The Royal Society," mentioned that the first English scientific writer on the possibility of flight was Bishop Wilkins, brother-in-law of Oliver Cromwell, and one of the founders of the Royal Society. The President, replying, referred to the recent celebration of the bicentenary of Captain Cook, whose first voyage resulted from the action of the Royal Society in presenting a petition to the King. Captain Cook's second voyage was followed by his election as a Fellow of the Royal Society. The toast of "The Guests" was proposed by Sir DANIEL HARRIS, and the ARCHBISHOP OF CANTERBURY and Sir BERKELEY MOYNIHAN responded. Sir Berkeley Moynihan said that the further advance of surgery depended entirely upon developments in science, though in many cases it was hardly possible to conceive the achievement of greater success than had now been won.

POOR LAW ADMINISTRATION

ANNUAL REPORT OF THE MINISTRY OF HEALTH

AN extract from the annual report of the Ministry of Health for 1927-28 containing the sections relating to the administration of the Poor Law, together with the reports of the general inspectors of the Ministry, has been issued separately. The full report, which did not contain the general inspectors' reports, was the subject of a notice in the *Journal* of September 8th (p. 453), but the extract which has just been published is of particular interest in its bearing upon the Poor Law reform proposals now before Parliament, and upon the important questions of hospital provision and of co-operation between voluntary and public institutions. The report provides a valuable study of the many problems connected with the administration of relief and vagrancy, but its main feature from the medical point of view is the information it gives upon institutions and institutional treatment.

There is an impression in many quarters that a surplus of accommodation exists in Poor Law institutions generally in order to procure accurate information on this subject a special return of the number of beds occupied and unoccupied, and of additional potential accommodation was obtained only this year at a time when the pressure for accommodation, especially for the sick, was at its highest. Separate returns were obtained for certain classes of special ward and the various establishments were grouped for analysis according to the type to which they belonged. In the first group, consisting of institutions for the sick only (separate infirmaries and sick asylums), there was a total of 37,500 beds of which 32,567 were occupied and 4,933 unoccupied. The margin of unoccupied beds is 12 per cent of the total but more than half this margin consisted of beds in special wards (for example, receiving, isolation, mental, maternity, tuberculosis wards). It is therefore suggested in the report that so far from its being the case that separate infirmaries can be relied upon without extension to meet any shortage of hospital beds they are as a whole dangerously near the limits of the accommodation required. In the establishments commonly known as general mixed workhouses the accommodation for the sick, which is well known to vary widely in suitability, excluding the specialized wards comprised 41,611 occupied beds and 8,265 unoccupied beds, but it cannot be assumed that the entire margin would be suitable for the reception of acute cases. In the infirm wards 21,522 beds were occupied while the unoccupied beds numbered only 2,770, in the maternity wards unoccupied beds numbered 2,666 as compared with 1,384 occupied beds. Among institutions for mental cases excluding those maintained by the Metropolitan Asylums Board and certain others there were 3,524 occupied beds and 193 unoccupied, in the observation and mental wards of separate infirmaries there were 2,060 occupied beds, and in those of the general institutions 12,162 occupied beds, the unoccupied beds numbering 334 and 1,633 respectively.

The reports of the general inspectors emphasize the points which these figures suggest. In East Anglia it is stated, the empty beds are not as a rule in the district where they are wanted, and the margins in certain areas are described as dangerously low. It is also pointed out that each institution must always have a margin, as it cannot refuse any destitute person, and further, that owing to subdivision each department must have a margin so that the total is considerable. At the same time, the general inspector observes that a smaller total margin would suffice if all institutions in each county were managed by one authority. The inspector for the area which includes London states that in the metropolitan area not only is there no margin of available beds in the Poor Law hospitals, but that their existing accommodation is often overstrained. Reference is made to the value of arrangements by which chronic cases and such cases as long standing fractures which the general hospitals cannot retain may be made available in guardians' hospitals for the instruction of medical students. Discussing the question of co-operation between voluntary hospitals and Poor Law institutions, the inspector suggests that such co-operation in any form at present advanced contains at least two fatal defects, an arrangement by which the general hospital took only acute cases, leaving the more chronic cases to the Poor Law hospitals would he believes, lower the standard of these institutions, and would also make it impossible to attract or train nurses. In this connection it is interesting to note that according to the report of the general inspector for the district in Bedfordshire, Berkshire, Buckinghamshire, Northamptonshire and Oxfordshire in the majority of the

unions close co-operation now exists between the Poor Law infirmary and the local voluntary hospital. Where provision is not made in the former for acute or surgical cases they are promptly transferred to the hospital, the cost of treatment there being met in a friendly way by an annual subscription from the guardians, no difficulty on the other hand, arises as a rule in transferring chronic cases from the hospital to the infirmary. The medical staffs, it appears, also co-operate freely.

The provision of increased accommodation is being undertaken in many districts, as is inevitable in view of the situation disclosed in the figures given above and in the more populous areas generally the standard of equipment and staffing in new infirmaries is being steadily raised, while many extensions and alterations are being made to existing institutions. Consultants of the first rank are being employed even more frequently than before, and it seems likely that this tendency will be accelerated by unification of control proposed in the Local Government Bill.

LEAD TETRA-ETHYL IN MOTOR SPIRIT

MEETINGS OF THE COMMITTEE OF INQUIRY RESUMED

THE Departmental Committee which, under Sir Frederick Willis's chairmanship, is investigating the use of lead tetra-ethyl in motor spirit resumed its sittings at the Office of Works on December 3rd. It may be recalled that the Committee was appointed by the Minister of Health on April 2nd, and that, after holding four public sessions, it issued an interim report (Cmd. 3159), in which it was stated that there were no reasons for prohibiting the use of ethyl petrol, so long as certain precautionary measures were maintained. A summary of the report appeared in the *Journal* of August 4th (p. 219).

At the resumed session Dr H. E. ARMSTRONG F.R.S., chemistry professor at the City and Guilds College, South Kensington, gave evidence, and, in reply to Sir Frederick Willis, said that, as a chemist, he had paid special attention to poisoning by lead chiefly in paints. He had acted in defence of the use of lead in paints having proved that no lead was volatilized from paint during drying and that the observed objectionable effect arose from the solvent (turpentine) present in the paint, and from vapours given off during drying owing to the oxidation of the oil. He had also studied the action on living plant tissues of neutral liquids generally slightly soluble in water, a class to which lead tetra-ethyl belonged and had called special attention to the danger attending the use of such liquids as solvents. His views on the subject were summarized in an article he contributed to the *British Medical Journal* on December 17th 1921 (p. 1042). He held, that in view of the policy that had long prevailed in this country especially the action taken by the Home Office to discontinue lead a highly poisonous substance such as lead tetra-ethyl should never have been admitted into general use. Industry should never have regarded the public use of such a substance as legitimate. He also objected to the use of the terms ethyl gasoline and ethyl petrol as misnomers and speciously misleading. Tetra-ethyl was not the only means of improving the quality of low grade petrol and there was a special need for its introduction. The proportion put into ordinary petrol might be small, but large proportions were reported to have been used in motor racing. The tendency of the motor industry was to work at higher pressure ratios, and it was to this possible large future use of the tetra-ethyl that he took special exception.

Professor Armstrong went on to say that he had studied with care the evidence given to the Committee by Dr. Edgar (see *British Medical Journal*, May 5th p. 770) but he believed the evidence from the American experiments to be of little value, because the attention there had been almost entirely directed to the discovery of evidence of lead poisoning. The action of the tetra-ethyl whose primary poisonous effect should be that of a neutral liquid not that of a compound acting through the lead it contained was in no way comparable with that of a lead salt and this aspect had received little, if any attention from the American observers. The question the public needed to have answered was whether it was desirable that the well known but often disregarded danger arising from exhaust gases should in any way be increased in gravity by the addition of lead to the fumes. It was a question of public policy. Why when we were seeking to purify our atmosphere should we add to the air a poisonous dust to serve private ends? He criticized the American experiments on the effects of the use of ethyl gasoline upon human beings on the ground that the evidence sought for was of lead poisoning and the ingestion of lead. It was stated that none of the individuals examined showed injury to health.

resulting in any way from ethyl gasoline. But what symptoms of injury were looked for? If there was no injury to health it meant that the exposure to the fumes was so slight as to be of no account, for petrol vapour was inimical to health when constantly inhaled. A vast amount of trouble seemed to have been taken to carry out experiments proving nothing.

What the precise behaviour of the lead tetraethyl would be was not yet clear. He showed the result of an experiment in which the substance had acted destructively on a leaf like any similar neutral liquid. At first, probably, it would act by disturbing osmotic balance and protoplasmic continuity. When decomposed the first change would probably be into lead triethyl hydroxide, but he did not think this would act specifically as a lead poison, and consequently the symptoms to be sought for were not those of lead poisoning. He commented upon 'a strange neglect' by the medical profession of the poisonous effect of neutral vapours. Owing to the mishaps early in the war to workers applying varnishes to various fabrics, precautions had been taken of late years to avoid this danger, but it was not sufficiently before the public.

Professor Armstrong concluded his main evidence by saying that he was no alarmist, but he had been all his life a student of the remarkable effects on chemical change produced by minute impurities, he knew that these could be very great, and he viewed with consternation the increase in the amount of the metallic poisons in public use, circulated in such a way that they constantly entered into food. Lead was everywhere to day, owing to the use of leaden pipes in conveying soft water. In this respect London suffered less than many places in the provinces, because it was blessed with a hard water supply. Arsenic and copper were creeping in everywhere, owing to their use in agriculture as fungicides and insecticides. Tin came in from canned goods. It might be that the increasing incidence of cancer was connected with metallic poisons. Boric acid, which had never been shown to be harmful to more than a few sensitives, was not allowed, although an invaluable preservative of food. Why should lead tetraethyl definitely very poisonous, be allowed with the object of protecting petrol, a far less worthy object of protection than food? He pleaded for a scientific policy in these matters, either a safe moderation or a uniform prohibition.

Sir GEORGE BUCHANAN, a member of the Committee, remarked that in the matter of lead paint and also of food preservatives, the Government departments concerned had taken a policy to which Professor Armstrong had been rather opposed, here their policy was one with which he might have been expected to agree, and yet he was in opposition again. Would not Professor Armstrong admit that this material had been used for a long time in the States and had been the subject of some painstaking medical investigations?

Professor ARMSTRONG replied that the inquiries conducted in the States had been imperfectly thought out, and in no way afforded the evidence needed to show that even when used in small proportion petrol mixed with lead tetraethyl was a safe fuel if used at all carelessly. In reply to Sir WILLIAM WILCOX, he expressed the opinion that very careful observation should be made during the next few years as to any symptoms of the kind not ordinarily associated with lead poisoning which might arise from the use of this material. He agreed with Dr W E DIXON who put a question to him on the subject, that the lead absorbed through petrol was probably negligible in comparison with the common use of lead in other ways, but it might easily not be so if tetraethyl came largely into use. He was told that in Italian trials the proportion reached 7 per cent, and although these might be said to be controlled conditions, it might happen—in the event of war, for example—that the substance would have to be handled under uncontrolled conditions. Dr DIXON pointed out a fallacy in the witness's analogy from boric acid. A preservative in food had to be eaten with the food, all of it, but there was no such necessary absorption of this liquid into the system, indeed the effort of all concerned was to prevent its absorption.

Sir CHARLES MARTIN thought that the report of the Surgeon General's department in the United States on the health of 350 selected persons employed in garages and in other lead industries, and controlled persons was the result of a very serious examination and one which called for a fine organization to carry out. Each person was examined for two hours by four physicians, and only a portion of the examination was specifically directed to the detection of possible incipient symptoms of lead poisoning.

Professor ARMSTRONG however still maintained that it was lead poisoning for which they sought. People went rabid on the lead boggy. M. Thomas the director of the International Labour Office during the Labour Conference at Geneva in 1921 in which the witness participated, could see nothing but lead for a whole month.

After Professor Armstrong had concluded his evidence the Committee in a private session, received evidence from Dr G Roche Lynch, senior official analyst to the Home Office.

MEDICAL MEMBERS OF LOCAL PUBLIC BODIES

THE following list contains the names of medical practitioners known to be serving as members of local authorities, or subsidiary public bodies, in Great Britain. Units are arranged in the classes to which they belong (county councils, county borough councils, urban district councils, etc.) in alphabetical order, with memberships of special committees containing a co-opted element, as in education and maternity and child welfare committees, shown under the parent body. Where possible, in the case of councillors and aldermen, membership of important committees and joint authorities is indicated. Addresses given are intended merely to identify the individuals concerned, and are not necessarily complete. It will be observed that a considerable proportion of those whose names appear in the list are members of more than one public body, and it is also interesting to note that in a number of the boroughs medical men are serving as mayors, while in Scottish towns several are burgh magistrates. The information embodied in the list has been received in response to a request published in the *Journal* during the past few weeks, it is probably far from complete, but serves to show that medical men and women are participating actively in the administration of about ninety local government bodies in various parts of the country, notably among the more important authorities.

ENGLAND AND WALES

COUNTY COUNCILS

Cambridge—Dr J H C Dalton, Cambridge (Alderman), Dr J W Ellis, Swavesey (Alderman), Dr W H Bunsall, Cambridge, Dr R Ellis, Cottenham. Co-opted members of committees: Dr J R C Canney, Cambridge (Midwives Acts, and Maternity and Child Welfare), Dr E D Adrian, Cambridge (Mental Deficiency), Dr C M Stevenson, Cambridge (Tuberculosis).
Cheshire, Dr H E Bower, Stretton (also Member, Mental Deficiency Acts Committee, Chester Asylum Committee, etc.).
Derbyshire—Dr W W Herbert, Heallys, Llangollen (Chairman, Mental Deficiency Committee).
Derbyshire—Dr G G Macdonald, Matlock (Alderman).
Dorsetshire—Dr C Grey Edwards, Parkstone, and Dr Oswald Rees, Abbotsbury.
Hertfordshire—Co-opted member of the Maternity and Child Welfare Committee: Dr K J Aveling, Watford.
Isle of Wight—Dr A W Harrison, Manoe, March (Member, Education, Public Health, Maternity and Child Welfare, Mental Deficiency, etc., Committees).
Lancashire—Member of the Education Committee, Area No 1: Dr T F Forster, Dalton in Furness.
London—Dr Stella Churchill, Chiswick.
Northumberland—Dr A S Hedley, Rothbury.
North Riding of Yorkshire—Dr A S Robinson, Redcar.
Pembrokeshire—Mr P A Lloyd, F.R.C.S., Haverfordwest.
Warwickshire—Dr E N Nason, Nuneaton (Member, Warwickshire and Coventry Joint Committee for Tuberculosis, Chairman of the Sanatorium Committee).
West Riding of Yorkshire—Dr T D Poole, Lanthwaite, near Huddersfield.
West Sussex—Dr H J M Milbank Smith, Worthing.
Wiltshire—Co-opted members of the Public Health Committee (Maternity and Child Welfare): Dr C E S Fleming, Bradford-on-Avon, and Dr F T Bond, Irowbridge.
Worcestershire—Dr F W J Conker, Bromsgrove (Chairman, Administrative Health Committee).

COUNTY BOROUGH COUNCILS

Birmingham—Dr W B Featherstone, Wyde Green, Dr L L Hadley, Acocks Green. Dr Wilson Hind, 106, Hagley Road, Dr J J Robb, Bourneville.
Blackburn—Member of the Education Committee: Dr Jeffrey Ramsay, 53, Preston New Road (Representative of the Victoria University of Manchester).
Bournemouth—Dr Walter Astlen, Bradley Road (Vice-Chairman Health Committee, Member, Education, Maternity and Child Welfare, Tuberculosis, etc. Committees).
Brighton—Dr Henry Gervis Stanford Avenue (Alderman).
Bristol—Dr E J Ball, Clifton (Member, Health Committee), Dr Lionel Page Tyndall's Park.
Bury—Dr I W Johnson, Red Bank (Chairman, Health Committee, Member, Education Committee).
Coventry—Dr I A B Soden, Queen's Road (Alderman, Chairman Public Health Committee, Member, Education, and Maternity and Child Welfare Committees).

Derby—Co-opted member of the Maternity and Child Welfare Committee Dr C E Potter
Ipswich—Dr J R Staddon (Alderman, Chairman, Mental Deficiency Committee)
Norwich—Dr G S Pope, Heigham Hall (Alderman, Chairman, Health, and Maternity and Child Welfare Committees, etc.)
Oxford—Dr H T Gillett, Dr William Stobie (Sheriff)
 Co-opted members of the Mental Deficiency Committee Dr Edwin Morton and Dr A G Gibson
Portsmouth—Dr P H Green, Mile End, Dr M H Wry, Southsea, Dr A B Wright, Southsea
Preston—Dr T H C Dorham (Alderman, Vice Chairman, Public Health Committee, Member, Maternity and Child Welfare Committee) Dr F W Collinson (Member, Public Health and Maternity and Child Welfare Committees)
South Shields—Dr E H Gibson, Laygate (Alderman)
Stoke on Trent—Member of Education Committee Mr Harold Hartley, F R C S (Representative of the Victoria University of Manchester)
Sunderland—Dr I G Modlin (Mayor)
Walsall—Dr E P Drabble, Bloxwich (Member, Health, and Maternity and Child Welfare Committees) Dr J F O Meara (Member, Health, and Maternity and Child Welfare Committees)
West Ham—Co-opted members of the Maternity and Child Welfare Committee Dr H S Beadles, Romford, and Dr P I Watkin, Camberland Road, E13
Worcester—Dr Arthur Foster, 85, Ombersley Road

NON COUNTY BOROUGH COUNCILS

Bishop's Cleeve—Dr John Adams
Brighouse—Dr James Wood (Member, Brighouse Joint Hospital Board)
Buxton—Dr C W Buckley (Alderman)
Daventry—Dr J C O Raftery (Alderman)
Henley on Thames—Dr W J Susman (Deputy Mayor)
Heywood—Dr George Geddes (Vice Chairman, Education Committee, Member, Health Committee)
Luton—Co-opted member of the Maternity and Child Welfare Committee Dr J W Bone
Nuneaton—Dr L E Price (Mayor, Chairman of the Health, and Maternity and Child Welfare Committees, Member of the Education Committee) Co-opted member of the Education Committee Dr E N Nason
Poole—Dr J R MacMahon, Parkstone (Member, Health Committee) Dr E O Scallion, Parkstone (Member, Health, and Maternity and Child Welfare Committees) Dr Charles Grey Edwards, Parkstone (Member, Health, and Maternity and Child Welfare Committees)
Redcar—Dr A S Robinson, Oulton
Wotford—Dr W P Porter (Chairman, Maternity and Infant Welfare Committee)
Worthing—Co-opted member, Maternity and Child Welfare Subcommittee Dr H J M. Milbank Smith

METROPOLITAN BOROUGH COUNCILS

City of London—Court of Common Council, Colonel R S Blackham
Hampstead—Dr S Monekton Copeman, F R S
Kensington—Dr Henry Robinson (Mayor and Alderman)
Stoke Newington—Dr L M. Ladell Dr H M Churchill

URBAN DISTRICT COUNCILS

Aberystwyth (Monmouthshire)—Member, Maternity and Child Welfare Committee Dr R J S Verity, Garndiffarth.
Beckenham (Kent)—Dr J H Bennett (Vice Chairman, West Kent Joint Hospital Board, Member, West Kent Main Sewerage Board, Higher Education, and Maternity and Child Welfare Committees)
Brentwood (Essex)—Dr A J Gibson, Dr C J L Mansel Bromsgrove (Worcestershire)—Dr F W J Coaker
Brounville (Staffordshire)—Dr James Stewart, Walsall Wood
Castleford (Yorkshire)—Dr L H Butler
Credon (Devon)—Dr George Rice (Chairman, Public Health Committee)
Egham (Surrey)—Dr J W Bird, Egham Hill (Chairman)
Hamley (Yorkshire)—Dr W H Smailes (Vice Chairman, Highways and Sanitary Committee)
Neston and Parkgate (Cheshire)—Dr George Gynn, Neston
Newton in Makerfield (Lancashire)—Dr Walter Latham, Newton le Willows.
Seaford (Sussex)—Dr C B Gervais, Shepway (Chairman)
Wimborne (Dorset)—Dr B R Parmer (Chairman)
Ware (Hertfordshire)—Dr W G Stewart (Chairman)
Windesham (Surrey)—Dr H Athill Crutwell, Bagshot (Chairman)

RURAL DISTRICT COUNCILS

Godstone (Surrey)—Dr A. P. Luff, Limsfield
Hoo (Kent)—Dr J A Shaw
Llandilo Fawr (Carmarthenshire)—Dr Joseph Shubbo, Llandellic.

Wympton (Devon)—Dr Alfred Turner
Solihull (Warwickshire)—Dr C R Lunn, Olton

BOARDS OF GUARDIANS

Bournemouth and Christchurch (Hampshire)—Dr F S. Coleman, Bournemouth
Coruon (Merionethshire)—Dr W W Herbert, Llangollen
Hoo (Kent)—Dr J A Shaw
Llandilo Fawr (Carmarthenshire)—Dr Joseph Shubbo, Llandellic
Plympton (Devon)—Dr Alfred Turner
Rochford (Essex)—Dr R A S Sunderland, Southend
St Vorylchone (London)—Dr Eleanor Lowry, 4, Devonshire Place, W
Solihull (Warwickshire)—Dr C R Lunn, Olton

PARISH COUNCILS

Thorne (Yorkshire)—Dr C Dorwent Walker

SCOTLAND

COUNTY COUNCILS

Bute—Dr J H Paul, Millport.
Clackmannan—Dr E E Dyer, Alloa (Chairman, Tuberculosis Committee)

TOWN COUNCILS

Edinburgh—Dr T G Nasmyth, Morningside (Baillie, Member, Public Health Committee)
Kingswae—Dr Felix Savy (Convener Public Health Committee)
Laurencekirk—Dr J C M Matheson (Convener, Public Health Committee)
Paisley—Dr W H Gibson (Baillie)
Sanguhar—Dr J K. Dnnlop
Tain—Dr E K Mackenzie (Baillie Member, Ross and Cromarty Tuberculosis Committee, and Joint Hospital Committee)

EDUCATION AUTHORITIES

Aberdeenshire—Dr Alexander Hendry, Ballater (Convener, Medical Inspection and Treatment Committee)
Selkirkshire—Dr E M Tyrrell, Galashiels (Chairman)

PARISH COUNCILS

Tom (Ross shire)—Dr E K. Mackenzie.

France.

[FROM OUR OWN CORRESPONDENT]

The Social Insurance Law

It is with a sense of great relief and gratification that the profession at large is given to understand that unity prevails again among us. The old Union of the Medical Syndicates and the young Federation are joining in a single confederation. We earnestly hope for the best, may a true confederal spirit inspire the very important decisions which have to be faced. There is no doubt that there is no more time to be lost in speeches; it is action that is needed. The law organizing compulsory medical insurance has passed through Parliament in such a shape that even its promoters consider it as stillborn. But the principle has been voted, and it tends towards turning nearly every practitioner into a State official, whose hands are bound with red tape. Such a situation has at last been fully realized by the profession, and has done more than anything else to bring them all under the same colours of revolt. A well known politician, speaking in his capacity as a member of the Government, says "I care nothing about the criticisms of the medical syndicates nor of their threats." It is now our duty to act so that he shall care. As a matter of fact, the tendency is to convert the practice of medicine in France into a State monopoly, to do with all forms of education what has been done in the past with tobacco and matches! This is what we are uniting to oppose.

B C G

The present discussions at the Academy of Medicine remind our elders of the heroic times when Pasteur had to fight for his new gospel. On October 23rd Calmette gave evidence in the case of a mining district in Northern France where every child had been vaccinated at birth. The general death rate fell to 3.5 per cent, against 8.8 per cent in the rest of the country. Professors Bernard, Debre, and Lelong have noted the effect of cutaneous reaction in 104 infants vaccinated and separated from all possibility of infection. The reaction proved positive in 50 per cent of

the cases, proving, according to them, the validity and the efficacy of the method of Calmette and Guérin. But M. Lignières, who is a member of the veterinary section of the learned Academy of Medicine, is far from being convinced, and basing the whole of his argument on the case of the young Denise¹ "This child was infected with B.C.G.," says he, "and here is the proof." "No," replies Calmette, "but by Koch's bacillus," and he recalls the 110,000 vaccinations of infants which have proved to be harmless and, as statistics show, efficacious. Dr. Le Lorrain supports the same views, and relies on his experience gathered from the 450 B.C.G. vaccinations carried out in his wards at Hôpital Boucicaut in Paris. Professor Leon Bernard comes to the rescue, quoting the conclusions of the special Commission of the League of Nations. The last word is said by Professor Roux from these investigations we are convinced that great progress is being realized. There is no doubt that the Academy of Medicine is all on the side of Calmette, but amply opposition and discussion are necessary in a question of such immense importance. Dr. Renault, in a most diplomatic sentence, described M. Lignières not as an adversary, but as a 'partisan modéré.' The discussion is to be continued, may it be serene though passionate!

Yellow Fever

At the Académie des Sciences Professor Calmette read an important note concerning the fight against yellow fever. Mr. Roubaud, following the experiments of Bacot, the British member of the Yellow Fever Commission, supports the view that the stegomyia does not lay eggs in pure water. It appears that the process of treating polluted water with chlorine (known in France as *verdunisation*) may prevent the hatching, and therefore this might prove a practical way of destroying the mosquito. It is by these means that the epidemic in Dakar this year was controlled. At the same time typhoid and amoebic dysentery should be checked, and this simple method devised by Colonel Banaoua will prove to be life-saving on a large scale.

Specialists in France

There is a strong movement towards some form of regulation as regards specialization. At the present time any registered practitioner may call himself a specialist in any branch of medicine. The public should be protected and be allowed to judge competence by some other means than the larger fee he has to pay. Our administration is considering the possibility of awarding certificates after special examinations. This is very much against tradition, but seems to protect the interests of the earnest specialist and of the patients. Such regulations exist in Hungary and in Czechoslovakia. In Germany the situation is controlled by the union of practitioners, three or four years of special post-graduate studies are required to make a specialist. Among the larger countries Great Britain and France stand together for perfect and dangerous freedom. The story is told of a French doctor, starting his career as an accoucheur, whose only qualification was having been ploughed seven times in succession at his final in obstetrics.

G. MORON

Union of South Africa.

[FROM OUR CORRESPONDENT IN PRETORIA]

Hookworm Among Rand Miners

ANKYLOSTOMIASIS is becoming a serious problem on the Witwatersrand gold mines, and an agitation has been set on foot for making it a compensatable industrial disease. Recently exaggerated statements have, however, been made by a section of the Labour party in their efforts to attain this object. The position briefly is that the deeper levels of most of the mines, where ideal conditions of warmth, moisture, and darkness obtain, have become infested by the native employees brought from Portuguese territory along the east coast. This region is tropical and is badly infested with hookworm. There are approximately 100,000 of these east coast natives working on the Rand gold mines—that is, they represent about half the total complement of native workers. A large number of faecal

examinations made at random indicated that about 50 per cent of the east coast boys (the generally accepted designation of a native worker) arrive on the mines harbouring the parasite. These boys tend to rid themselves of the infection after arrival on the mines without any treatment. Examinations of untreated east coast boys who had worked on the mines for from four to six months showed that the infection had dropped from 50 per cent to something in the neighbourhood of 15 to 20 per cent. This is readily comprehensible from the history of the worm, if it is assumed that reinfection does not occur. The curious fact, however, is that European miners working under the same conditions underground tend to contract the disease. Since, under similar conditions, the native worker tends to rid himself of the disease and the European worker to acquire it, the only obvious explanation appears to be that the European skin is more penetrable or attractive to larvae than the Bantu skin.

An investigation made by the Union Health Department last year showed that, apart from the Zululand and Natal coasts (in which regions the heavy infestation of the Portuguese east coastal zone tails off), infection is very unlikely to occur anywhere in the Union on the surface. All European mine workers found to be harbouring the parasite may, therefore, be assumed to have become infested underground. In November, 1926, cases were detected among European miners by the Miners' Phthisis Medical Bureau at its routine examination of all European miners, which takes place at intervals not exceeding six months. Since that date and up to the end of last September, 309 cases among Europeans have been detected, either as the result of the periodic examinations by the bureau or by examinations made in the research laboratory of the Rand Mines, Limited. It is improbable under present conditions, with medical officers along the reef and the alert, that many cases among Europeans escape detection. The procedure at the bureau since November, 1926 has been to issue advisory letters to such miners as appeared to be suffering from noticeable anaemia, advising them to consult their own doctors, with the suggestion that the condition might be due to hookworm. The mine chiefly affected is the City Deep, which employs over 1,000 Europeans. Of the 309 cases, 222 were among miners working on this mine at the time their condition was detected.

On October 14th a deputation from the South African Mine Workers' Union to the annual provincial conference of the Labour party in Johannesburg solicited the party's support in the effort being made to have hookworm declared an occupational disease, and so carry compensation. The deputation stated that the scourge of hookworm was sweeping the Rand mines, that on the City Deep above 75 per cent of the white underground workers were affected, and that the cure was worse than the disease. The president of the Mine Workers' Union stated that the cure for the disease had such severe effects on the human system that in 99 per cent of cases some other ailment was left after the cure had been completed, saying that he would rather die than be cured in the way some of these men had been cured, they were left useless physical wrecks, able to do nothing. Another executive officer of the union said that hookworm disease was worse than phthisis. He also affirmed that the cure was far worse than the disease, and was dreaded by the sufferers. The conference undertook to have the matter dealt with by the parliamentary caucus of the Labour party, and appointed a parliamentary deputation to accompany Mine Workers' Union representatives to interview the Minister of Mines and the Minister of Health.

Dr. A. J. Orenstein, superintendent of sanitation, Rand Mines, Limited, in a press interview the following day, denied the allegation that the disease was spreading. In the fifteen months during which they had been combating it the incidence had considerably decreased. To say that the cure was worse than the disease was manifestly incorrect. The cure normally took four weeks, it was unpleasant but it had no ill effects and did not induce any other complaint. The answer to the assertion that it was worse than miners' phthisis was that death from hookworm was a rarity. With regard to the demand that the condition be declared an occupational disease, he said that

¹ See *British Medical Journal*, November 24th 1928 p. 850.

all men laid off with the disease were given *ex gratia* half-pay, as they would if the disease were officially an occupational one. Moreover, to relieve the strain on the benefit societies, all medicine and hospital expenses were paid. All places underground where infection was possible were now being treated with salt. This had caused a great decrease in the incidence of the disease.

The New Union Medical Council

With the publication of the result of the poll the formation of the first Medical Council of the Union of South Africa was completed, and the Council met for the first time on October 22nd in Pretoria. The ten medical members elected by the profession are Dr W Dailey-Hartley, for many years editor of the *South African Medical Record* (who headed the poll), Sir F Spencer Lister, Drs D J Wood, R P MacKenzie, A W Sanders, M R Drennan, C Porter, W T P Davies, A McKenzie, and S M de Kock. Drs A W Watt and J van Niekerk, both resident in the Transvaal, received more votes than Dr de Kock of the Orange Free State, but could not be given seats, as four Transvaal members had already been elected, it is laid down that not more than four medical practitioners who are members of the Council shall be ordinarily resident in any one province of the Union. The distribution of the elected members among the four provinces is as follows: Transvaal 4, Cape 3, Natal 2, Orange Free State 1. Previous to the election an official Association "ticket" had been formed by the Federal Council of the Medical Association of South Africa (B M A) by the simple process of asking every Branch to nominate candidates. The principle of such a ticket was severely criticized by a certain section of the profession. The fifteen names of practitioners nominated by Branches were submitted by the Association for the guidance of the professional electorate. Six of these headed the poll and eight in all were elected to the Council, only two practitioners not on the original ticket succeeding in obtaining election. The dental members of the Council elected by the dental profession in South Africa are Messrs Walter Flord, Clav J Bullis, and B M Hunter. The nursing profession returned as its members Miss Alexander and Mrs Bennie. The two *ex officio* members of the new Council are Dr J A Mitchell, Secretary for Public Health, and Dr J T Dunston, Commissioner for Mental Hygiene. The members nominated by the Minister of Public Health are medical, Dr A J Stals, M L A, and Dr H F Fernandez, dental, Mr J A Stegmann, L D S, lay, Messrs F W Douglass, K C, and W H Rood, M L A. The University of the Witwatersrand is represented by Professor J Watt, and the University of Capetown by Mr E B Fuller, F R C S Ed.

The First Session

The Council was formally inaugurated by the Rev Dr D F Malan, Minister of Public Health, who remarked that he was in a certain sense a member of the medical profession because, as Minister of Public Health, he had assisted at the birth of the Act. Dr Davies later, in warmly thanking him for his encouraging address, remarked that the Minister had honourably maintained the traditions of the profession as accoucheur in this capacity.

No measure, said Dr Malan in his opening address, had ever had a more chequered career in the history of South African legislation, or had encountered more difficulties in its passage through Parliament. It was seven years after Union before any attempt was made at consolidating the medical laws of South Africa, and from 1917 onwards the bill which had now become law had figured on the order paper. The measure had, however, eventually reached the statute-book with practically the unanimous support of all parties in Parliament and the profession and the country generally were to be congratulated. He particularly welcomed the two lay members of the Council. From the beginning of the world the burden of the care of the sick had fallen on the feminine section of humanity and the time had come when men could no longer regard their presence on governing bodies as an encroachment on male prerogatives. Women had come to stay, and he could not visualize any future medical council without women members. Dealing with the delays

in the passage of the reforms introduced by the Act, Dr Malan said these had caused great inconvenience to the Government departments administering public health, as well as injustice to the profession, and had allowed a number of abuses to become so entrenched that it became difficult to eradicate them. But there were corresponding advantages. It enabled the bill to be subjected to a close scrutiny by Parliament, by the professions affected, and by the public, such as few legislative proposals ever received. This resulted in the elimination of defects which might otherwise have escaped notice. Indeed, the Act in its present form was so highly thought of that practically without amendment it would be applied to the mandated territories of South-West Africa by proclamation from January 1st next, while the Government and Parliament of Southern Rhodesia had taken it over with a few minor adjustments to meet local requirements and conditions. While it was true in some respects that the Act was one for the protection of certain professions and callings it would function primarily in the interests of the public generally. It was impossible to maintain the high standard of efficiency, of moral character, and action required of the medical profession unless it was properly protected and had a governing body to exercise discipline. The Medical, Dental, and Pharmacy Act could justly be regarded as the Magna Charta not only of the medical profession, but of the public, for Parliament had thought fit to have the general public represented on the Council by two lay members. He hoped, in conclusion, that they would look on the Act in that light, and that they would be worthy of the great trust imposed on them, and assured them of his deep personal interest in their work. After due acknowledgement of his stimulating address the Minister withdrew. Dr W T Davies was unanimously elected president, and Dr S M de Kock vice-president, of the Council.

Scotland.

Health of Scotland

Dr WILLIAM ROBERTSON, medical officer of health for Edinburgh, on November 28th, gave a popular lecture upon "Some points in public and private health." He said that our forefathers bequeathed to us wretchedly planned communities with narrow streets lined by ill assorted buildings, erected in more or less haphazard fashion. Some two hundred years ago there were no drainage systems, and no water supplies save those provided by wells, which were often so greatly polluted that they disseminated widespread epidemics of enteric fever and cholera, there was no scavenging system worth mentioning, and domestic animals often shared the homes of the citizens, there were no fireplaces in the houses of the poorer classes, and no carpets or linoleums. Straw littered the floors, and became the breeding-places of vermin and the dumping ground of household refuse. We were now trying to erase the blot which had been left behind, and before another century had passed this country would have advanced much further in its fight against disease, dirt, overcrowding, and bad housing conditions. The men, women, and children of two hundred years ago were constantly menaced by the multiplicity of dangers against which the citizens of the present day found themselves surrounded by innumerable safeguards. No one could say that there was not still room for improvement, but preventive medicine could not be forced upon the individual, who must be educated to lend a hand in the all round social uplift now occurring. The glaring physical defects revealed by the critical examination of the manhood of the country which had been rendered necessary by the great war substantiated the arguments of those who insisted that the conditions of living had not been conducive to building up an A1 population. The infantile mortality figures of two hundred years ago showed that 250 to 300 children died out of every 1,000 born, but the figure had now been reduced to 80 per 1,000. Notification of births, armies of health visitors, toddlers playgroves, physiotherapy centres, convalescent homes, and sick children's hospital all functioned in building up healthy children and in

emerging any who developed disease. There were now well-appointed schools with abundance of light and ventilation, there were facilities for recreation which made school life congenial and interesting, and every school had its physical instructors. All these factors were advancing the well-being of the boys and girls who would, in the near future, grow up to be men and women of much higher physical standards than had provided in the past. Those who had laboured at the present day under what might be called ideal conditions of airy workshops with good light, ventilation and welfare supervision might consider themselves fortunate. For the adult population no wanted good wages, good food, and good housing. Efforts must be made to persuade the people of this country that high prices did not necessarily bring the best food values. Headway was being made in this direction, many persons were learning the lesson that heavy feeding was a failure from the standpoint of benefit to health, and that simple fare in moderate quantity and suitably combined would improve health and prevent the onset of disease. Well planned houses surrounded by plots of open space were also contributing to better general health. There were now 15,000 panel practitioners in the country, 18,000,000 persons were insured, and £15,000,000 was being annually spent in connexion with national health insurance. Nevertheless millions of pounds in wages were lost every year on account of minor ailments, the Health Insurance Act provided mainly for diseases after they had begun, and one might feel confident that the next great step forward in preventing ill health would be taken when periodical medical examination was put into operation. This would follow naturally upon the principle of the systematic medical inspection of school children. The lecturer considered that the welfare of the nation was progressing at a satisfactory rate, and that it only remained for the individual to take advantage of all the opportunities available to him.

Scottish Asylums Pathological Scheme

The annual report on the working of the Scottish Asylums Pathological Scheme, which is supported by contributions from twenty institutions, gives an account of the work carried on by the pathologist, Dr F. E. Reynolds, who, in addition to reporting upon 204 specimens sent to the laboratory, has made several visits to mental hospitals for consultation with members of the staffs. As lecturer in neuropathology Dr Reynolds has conducted his usual course of lectures at Edinburgh University for the diploma of psychiatry. In the course of the year a series of investigations into paths of infection of the central nervous system, undertaken in association with Dr Logan Turner, was concluded, important results have already been published from time to time, and the completed work is now being collected into a monograph on the subject. Dr Reynolds is at present engaged, in conjunction with Dr James K. Slater, in a further research on the healing of lesions of the central nervous system. A preliminary study has already been published. The revenue of the scheme during the year amounted to £1,865, including a grant from the Medical Research Council, and a payment from Edinburgh University towards the salary as lecturer, while the expenditure for the year was £1,176.

Phrenology and Criminology

The annual lecture under the William Ramsay Henderson Trust was delivered by Dr Norwood East, medical inspector of H.M. Prisons in Lugdun and Wales, in the anatomy classroom of Edinburgh University, on November 30th, when Dr H. C. Marr presided. The Trust exists for the promotion of phrenology, and the lecture formed part of the celebrations of the centenary of the death of Dr Francis Joseph Gall. The lecturer first dealt with the work of Dr Gall, who was born at Tiefenbrunn, Boden, in 1751, and died in 1828, saying that his centenary was of peculiar interest to the student of criminal problems, as he had been described as the founder of criminal anthropology. It was necessary for the criminologist to distinguish his important anatomical and physiological studies of the brain from the cranioscopic portion of phrenology. The anatomists Reil and Loder, for whom Gall had dissected several brains, had given him unstinted

praise, while Curvier, Flourens, and Geoffroy St Hilaire had paid similar tributes to Gall's anatomical and physiological studies. Sir Henry Head, in our own day, had pointed out that no one was really indebted to Gall for the beginning of the conceptions now held regarding the relation of the various portions of the nervous system to one another. Nevertheless Gall's hypothesis that the so-called organs in the brain could be studied through the impressions they were supposed to make on the shape of the cranium was no longer generally accepted, and the assumption that the development of organs of combitiveness, destructiveness, benevolence, and so on were indicated by the contour of the skull, and that this matter was of service in the diagnosis of criminality, appeared now a fanciful speculation. Gall was physician to the lunatic asylum at Vienna, and had special opportunities for clinical observation. Whenever possible he compared, by post-mortem examination, the relation between the shape and size of the brain and the head. He also experimented on animals to ascertain the effect of the removal of portions of the brain. In 1800 he was joined at Vienna by John Caspar Spurzheim, the two were associated in joint researches, and published important works on the anatomy and physiology of the nervous system. In Edinburgh the brothers George and Andrew Combe were induced by Spurzheim to become advocates of phrenology, and George Combe wrote numerous works on the subject. In 1821 the Edinburgh Phrenological Society was founded, and published a journal from 1823 until 1847, in which several important papers dealing with the diagnosis of criminality had been published. The phrenological explanation of crime was succeeded, Dr East continued, by Lombroso's anthropological investigations, upon which he founded his doctrine that the criminal was an atavistic anomaly presenting definite morbid physical stigmata, and clearly differentiated from those who were not criminals. At the beginning of the present century medical officers of the English Prison Service conducted a series of anthropometrical investigations upon 3,000 convicts; the material was tabulated by Charles Goring, and the publication carried out under the direction of Professor Karl Pearson in 1913. As a result of comparing criminals with each other, and with law-abiding citizens, Goring found no evidence to confirm the view of Lombroso that there was a definite criminal type. The differences in head measurements was found not to be substantial. The decline of phrenological and anthropometrical interpretation of criminal conduct was succeeded by psychological methods of investigation, and it was found that much anti-social conduct had its counterpart among the normal and law-abiding community. It was also found that the criminal might be no mental weakling, but a man of courage, determination, and resource, although a certain number of those who committed crimes were mentally abnormal and suffered from mental deficiency or constitutional inferiority. These were, however, a minority, and the vast majority of crimes were committed by the "man in the street." Medical and sociological investigations had contributed towards a knowledge of character formation, its environmental and inherited influences and emotional disharmonies, and had helped to bring them nearer an understanding of criminal antecedents and purposes.

Milk as a Food

Dealing with the subject of milk as a food in a lecture given recently in Edinburgh, Mrs Chalmers Watson, M.D., said that Nature had endowed the cow with a milk capacity to rear one, or at most two, calves in the course of its lactation, but science and skilled feeding now produced cows which gave as much milk in a lactation period as would rear at least a dozen calves. The amount of milk consumed in this country still fell far short of that obtaining in other places, and yet good milk was, in proportion to its cost, one of the cheapest foods. This subject had special application to the expectant mother, the infant, the growing child, and the sick person. The protein in one quart of milk was equal to that present in seven ounces of salmon steak or three and a half ounces of fowl, and the energy value in the same amount of milk was equal to that of twelve ounces of steak or ten ounces of fowl. As a food for adults milk was restricted only

because of its bulk, but people would enjoy greater physical health and mental vigour if they would substitute a tumblerful of milk for other food. The lecturer particularly recommended that housewives should purchase certified milk for drinking purposes and pasteurized milk for general household use. She added that indications pointed to our being on the threshold of new and important knowledge of the influence of vitamins in food and of sunshine in relation to food. It had long been recognized that milk from cows fed on good pasture had much higher nutritive value than that of stall-fed cows, and we now had the scientific explanation of this fact. Successful attempts had recently been made to impart therapeutic qualities to milk by irradiation with ultra-violet rays. In other directions experience had showed that milk artificially soured on lines laid down by Metchnikoff also possessed valuable properties for the treatment of a large number of diseases. She considered that a full appreciation of the special value of fresh clean milk of high standard was the first essential in the general campaign of preventive medicine, to which attention was now being generally directed.

Inverness District Asylum

The sixty-fourth annual report by the superintendent of the Inverness District Asylum, Dr. T. C. Mackenzie, which has just been issued, shows that on May 15th there were 729 persons on the books of the asylum, of whom 720 were resident and 9 absent on probation. The total number of cases under treatment during the previous year was 858, admissions numbered 135, discharges 73, and deaths 56. Of the patients admitted during the year 41 had been previously under asylum treatment, giving a readmission rate of 30.3 per cent, and 15 were aged 70 or over. With regard to the type of mental disorder, 54 were cases of melancholia, 30 of mania, 32 of secondary dementia, 22 were associated with senile decay, 10 were cases of dementia praecox, 5 of congenital mental deficiency, and 4 of general paralysis. A hereditary predisposition to insanity was found to exist in 56 out of the 135 cases admitted, and in 54 of these there had been at least one previous attack of mental disorder. Senility was among the assigned causes in 34, and alcoholism in 2, of the cases. The 73 patients discharged, after removal on probation, included 47 discharged as recovered, giving a recovery rate on the admissions for the year of 34.8 per cent for both sexes. The 56 deaths gave a death rate of 7.8 per cent, and of these phthisis accounted for 12 and senile decay for 17 cases. The asylum farms continued to supply much produce, and a large number of patients were employed in various ways on the farms and gardens.

Edinburgh Royal Infirmary

At the tenth annual general meeting of the League of Subscribers to the Royal Infirmary of Edinburgh, held on November 27th, Mr. James Campbell, who presided, stated that a provisional order of the town council would, before long, entitle the league to elect two managers to the Infirmary board. The report of the secretary showed that £21,435 had been received in the past financial year from 1,450 groups of subscribers, £16,000 having been collected in the city and the remainder in the surrounding district. Subscriptions from this source had now been stabilized in the neighbourhood of £21,400 for the past four years. Including the league and groups of miners, some 120,000 persons were now contributing regularly and systematically to the funds of the Royal Infirmary. Of the subscribing groups the largest was that of employees in the L. N. E. R. Company, whose contributions amounted to £2,129, as compared with £230 some ten years ago. The employees of the corporation provided £1,090, against £67 in 1913. During the ten years in which the league had been in operation it had collected a total of £180,000, which approximated to half of the original cost of building and equipping the hospital. Sheriff Brown, K.C., in a statement on behalf of the board of managers, said that the number of patients treated in the wards of the Infirmary during the past year was 19,680, an increase of nearly 1,000 over the preceding year. Approximately 8,800 patients came from the city and 9,900 from outside. At the out-patient department 62,085 patients were treated, an increase of 1,530 over those of the previous year. It was

hoped that the Astley-Ainslie Institute would be fully opened for use in the coming spring, and this would be a great source of relief to the Infirmary, because 150 more beds would be at the disposal of the patients and the institution. The ordinary income showed an increase of more than £5,000, and although a larger number of patients had been treated, the ordinary expenditure showed a reduction of £3,708. The waiting list still caused some concern, as its average exceeded 2,000 persons.

The Life and Work of Matthews Duncan

The first meeting of the eighty-eighth session of the Edinburgh Obstetrical Society was held on November 14th, when Dr. Haig Ferguson delivered his presidential address on Matthews Duncan. The choice of subject was of special interest to the Fellows of the Society, since Matthews Duncan became an ordinary Fellow in 1848, was elected a vice-president for the years 1872-73, and became president in 1874. The choice was further enhanced by the fact that Matthews Duncan was personally known to Dr. Haig Ferguson. After a vivid recollection of his personal character Dr. Haig Ferguson dealt with Matthews Duncan's early life, and his outstanding career at Marischal College, Aberdeen, where he carried everything before him. His relation with Sir J. Y. Simpson was then mentioned, and a great point was made of his intimate connexion with the discovery of chloroform—a fact which was not very widely known. An accurate account of his valuable publications and addresses was given, and extracts from his diary were read which helped those present to realize what a great man Matthews Duncan was and how advanced were his ideas. His life in Edinburgh was fully dealt with, and the lecturer commented on the great loss sustained by Edinburgh on his departure to London to take up an appointment at St. Bartholomew's Hospital. In London he had enjoyed a larger sphere of work, and his marvellous gift and pleasure in teaching the younger generation was turned to full advantage. It was interesting to note that however busy he was in London he was never too busy to receive friends from Edinburgh, and to enjoy a "crack" about Edinburgh affairs and his old Edinburgh friends. Dr. Haig Ferguson concluded his address by emphasizing the direct simple nature and the true Christian faith that upheld so great a man, who was not only one of the most famous gynaecologists that there had ever been, but one of the great personalities in medical history.

Ireland.

Free State Medical Registration Council

At the November session of the Irish Free State Medical Registration Council the president, Dr. Denis J. Coffey, said that at that meeting, as the first session of the Council for general business following the establishment of the Register under the Medical Practitioners Act, 1927, it was convenient to refer briefly to the work of the Council from the date of its appointment under the Act. He recalled that the Council had held its first meeting on November 1st, 1927, and he reviewed the steps taken in connexion with the Register, which was duly established on May 26th, 1928. The result, he said, had been that on the date of the establishment 4,068 names were on the Register of Medical Practitioners for Saorstát Éireann, of this number something less than one-half were registered by right of registered address in the Saorstát, and approximately 2,100 of registered address outside Saorstát Éireann by application in accordance with the Act. All these registrations were effected free of charge. Subsequent to establishment—that is, from May 26th, 1928—names might be registered only on payment of the ordinary fees. Since the establishment of the Register several committee meetings had been held, and one meeting of the Council was called for the special purpose of the appointment of three members to act on the Dental Board. Registration was now fully in operation under the Act. The attention of all newly qualified practitioners was therefore directed to the provisions of the Act concerning registration, from which it followed that a medical practitioner who was not registered might not sign any certificate required for the

purpose of any Act in force in Saorstát Éireann, and might not recover fees in any legal proceedings for professional attendance. Registration under the Act was effective only within the jurisdiction of Saorstát Éireann. The powers of the Council under the Act enabled them to remove from the Register any person convicted of a felony or misdemeanour, or proved, to the satisfaction of the Council, to have been guilty of infamous conduct in a professional respect. The Council might, from time to time, send by post to every person a letter inquiring whether he had ceased to practise or had changed his address. If no reply was received within six months the name might be removed from the Register. The agreement embodied in the Act between Saorstát Éireann, Great Britain, and Northern Ireland provided for the co-ordination of the disciplinary powers exercised by the Medical Registration Council and the General Medical Council. In respect of these powers it might be said that they were similar in character to those with which registered medical practitioners were familiar previously in the Medical Acts affecting the General Medical Register. In respect to the Register of Medical Practitioners in Saorstát Éireann similar general provisions, therefore, remained in regard to the maintenance of the Register, and in respect of offences or charges which might arise from the operation of the powers of the Medical Council of Saorstát Éireann. Similarly, in respect of medical examinations and the courses of study leading to the qualification under the licensing bodies in Saorstát Éireann, the Medical Council was charged with obligations of similar character to those of the previous Medical Acts, and for the exercise of all of these functions regulations had been duly made. Under other provisions of the Act occasions might arise for a recognition by the Executive Council of Saorstát Éireann, on the recommendation of the Medical Registration Council, of the extension of reciprocity of foreign countries or Dominions under stated conditions. The periods appointed in the regulations for ordinary meetings of the Council are in November and May. The first printed *Irish Medical Register* will, it is intended, be published early in the coming year. Meanwhile the actual work of registration is conducted at the temporary office, Room 123, Custom House Dublin. Dr Coffey expressed the indebtedness of the Council to the Registrar of the General Medical Council and his staff for their assistance at all times in furnishing information required by the Council in connexion with the establishment and maintenance of the *Irish Register*.

Medical Certification Pool Area in the Free State

General R. Mulcahy, Minister for Local Government and Public Health in the Free State, on November 30th, received the deputation appointed by the Irish Medical Committee to discuss with him the proposal recently made by the National Health Insurance Commission to change the pool area for the distribution of remuneration for medical certification from the dispensary district to the county. The Minister was accompanied by Mr. E. P. McCarron, Secretary of the Department, Sir Joseph Glynn, chairman of the National Health Insurance Commission, and Dr. W. J. Maguire, medical member. The deputation consisted of Dr. T. Hennessy, honorary secretary of the Irish Medical Committee, and Drs. R. J. Rowlette, H. J. Raverty, and J. P. Shanley. Dr. J. Power, chairman, and Mr. C. H. Gick, secretary of the Committee, were unavoidably absent. When the deputation had put before the Minister the reasons which led the Irish Medical Committee to decline to recommend the proposal of the National Health Insurance Commission for acceptance by the certifiers, Sir Joseph Glynn explained the reasons which induced the Commission to formulate the scheme. After a long discussion the Minister agreed to defer any change in the mode of payment until he had had time further to consider the present system as compared with alternatives which might possibly be preferable administratively, and more equitable to the certifiers. He commented on the present cost of distributing the £37,000 for medical certification, referring to the fact that the cost to the State of medical certification was one-tenth of the total inclusive cost to the State of national health insurance and its administration.

England and Wales.

The Hospital Saving Association

The Hospital Saving Association continues to make progress. In July, 1928, there were 764 groups, representing 62,000 contributors, from whose contributions of £22,000 the sum of £17,000 was paid to various hospitals and other institutions. In the year ending July 31st, 1928, over £240,000 was collected from 450,000 contributors in more than 5,000 groups, and the payments for hospital services amounted to £175,000. The annual meeting of the Association on November 28th attracted a very great number of group secretaries, so that the large Kingsway Hall seemed to be completely filled. The chairman, Sir Alan Anderson, said that at the present time the rate of income of the association was over £300,000 per annum, which meant the collection of two million threepences every month. If employers were to add one penny a week to the contributions of each of their workpeople the whole of the charitable contributions to some hospitals towards the maintenance of the association patients would be relieved. While there had been in the past year an increase of 10 per cent in the number of contributors and their dependants treated as in-patients, the fall of 8 per cent in the out-patients showed, said Sir Alan Anderson, that the Association was not abusing hospital treatment to the detriment of general practitioners. Sir Berkeley Moynihan, P.R.C.S., who had succeeded Viscount Cavo as vice-president of the association, described early efforts made in Leeds to establish a working people's hospital fund. He urged also the importance of maintaining the voluntary system, and illustrated the effect of the traditions of hospital training on the doctor's life, with a panegyric on Harvey, Hunter, and Lister. Mr. J. H. Thomas, M.P., combined a good deal of sentiment with a little badinage. He told an affecting story of a domestic servant who collected £50 in coppers for a hospital, and he followed this up with a refusal to be drawn by Sir Berkeley Moynihan into informing the meeting as to the fate of the voluntary hospitals after next June 1.

Gift of £50,000 for Radium for Hospitals in London

An offer from Sir Otto Beit of a gift of a sum of approximately, but not less than, £50,000 for the purchase of radium has been accepted by King Edward's Hospital Fund for London. Sir Otto Beit, in the letter containing the offer, states that recent personal observation has greatly impressed him with the value of radium as a remedial agent, and that, realizing that the hospitals of London are not in general adequately supplied, he has decided to place the sum mentioned at the disposal of the Fund for the purchase of radium. It is his wish that the Distribution Committee of the Fund, assisted, if necessary, by members of the medical profession co-opted *ad hoc*, should decide upon the proportions and manner in which the gift should be applied by way of the loan of radium to hospitals within the area of the Fund. In their selection of hospitals he desires the committee to have regard to competence of the staffing and equipment of the respective radiation departments, to an undertaking by the hospitals to ensure the safe custody of the radium loaned to them, and to insurance to its full value with an approved company. In the conclusion of his letter Sir Otto Beit recalls that he has for many years aimed at encouraging research in science and medicine, and states that he should like the committee to endeavour to secure that the hospitals so provided on loan with radium should be preferably those in which the cure of disease or the alleviation of suffering is associated with a keen interest in the furtherance of knowledge "for the relief of man's estate."

London Mental Hospital Superintendents

Ewell Colony, which since its evacuation by the Ministry of Pensions nearly two years ago has been used by the London County Council for the accommodation of patients certified under the Lunacy Acts, is now definitely to be continued as one of the London county mental hospitals. So long as the temporary arrangement was in force it was

not possible to appoint in a permanent capacity the principal officers, including the medical superintendent, necessary for the administration. It is now proposed to appoint as medical superintendent of the Exall Colony Dr L H Wootton, the deputy medical superintendent of Colney Hatch Mental Hospital, who, during the last two years, has been seconded to act as medical superintendent of the Colony. His salary will be £800 a year (based on pre-war conditions), with unfurnished house (rates, taxes, and water free). With the temporary additions at present in force the salary is £981 a year. Permission has been given for the medical superintendent of Horton Mental Hospital (Dr J R Lord) to hold the honorary appointment of lecturer in clinical psychiatry on the staff of the London School of Medicine for Women for a period of twelve months, subject to the conditions that the appointment shall not interfere with the efficient discharge of his official duties, and that the Council will not be held responsible for views or opinions expressed by him. This follows a request by the Royal Free Hospital, with which the London School of Medicine for Women is associated, for facilities to be given at Horton Mental Hospital for clinical instruction in psychiatry for their medical students, and for the medical superintendent to be allowed to hold an honorary appointment on the school staff.

Correspondence.

RADIUM AND CANCER

SIR,—The letter published in your issue of December 1st (p 1008) from Mr Malcolm Donaldson, and also your annotation, are most opportune, and should be carefully read and digested by every surgeon who proposes to use radium in the treatment of any case of cancer. The wave of enthusiasm of this line of treatment owes much of its origin to the discussions during the recent International Conference on Cancer organized by the British Cancer Campaign, but it should not be forgotten that the results then published were the results of many experts who had used radium for some years and who had slowly evolved a form of treatment from the experience gained in this form of work.

Together with my colleagues at the Cancer Hospital, I have used radium in the treatment of cancer for many years, at first with disappointing results, more recently, however, with improved technique and with the use of small rather than with massive doses, I have obtained many astonishingly good results. I might add that radium was first used for the treatment of patients at the Cancer Hospital as long ago as 1903.

I look upon cancer as a generic term covering many forms of malignant disease which as yet are not differentiated some of these are amenable to radium therapy and some are not, and only the experience of the surgeon seeing many of these cases will decide the question of the suitability of the individual case for this line of treatment. The indiscriminate use of such a remedy in the hands of many will only bring discredit on the work which is being done. It must not be forgotten that radium is a dangerous element. I have seen several cases of severe radium burns, and have had to amputate the thumb of one radium worker for epithelioma caused by it.

There is undoubtedly an urgent need for further supplies of radium in this country, and at the Cancer Hospital we urgently require much more than we possess at present to carry on our work. I would make a plea that treatment of cancer by radium should be encouraged to the full, but let it be in centres which are adapted for that purpose and which have attached to them not only surgeons, radiologists, and pathologists who are familiar with radium work, but also competent physicists to deal with the element.

Much work requires to be done yet before we can hail radium as a cure for cancer and I anticipate many changes with respect to dosage, filtration, etc., will take place before it is put on a sound foundation. Further, we have

yet to learn whether to use the element or its salts, or whether to rely upon radium emanation, and each case must be considered individually.

For the above reasons I do most emphatically agree with Mr Donaldson that we should not lose our sense of proportion and be carried away by the wave of enthusiasm which may lead to reaction and to disappointment, but for the present let the work be carried on in recognized centres suitably equipped, and assisted when possible by additional supplies of radium. Another point arises in connection with this—namely, the overhead charges necessitated by the use of radium are much the same, whether small or large amounts are handled, and therefore the economic value of the use of the element in centres is evident—I am, etc.,

London W 1, Dec 3rd

R H JOCELYN SWAN

SIR,—In the *Times* of November 20th there appeared a leading article on cancer which contained a quite unjustifiable and improper pronouncement. I immediately addressed to the Editor of the *Times* the following letter.

'In your leading article of to-day a issue dealing with cancer it is stated that "It is now universally acknowledged that the treatment by radium is the best possible treatment in cases of cancer of the womb and that surgical operation in this form of cancer is no longer advisable when radium can be obtained." This statement is at present quite unjustifiable for no statistics from British sources are extant to warrant such a sweeping conclusion. The probable truth is that there are certain cases best treated with radium and certain others best treated by operation and our present task is to discriminate between the two classes. A good many years further experience with radium will be required before a decisive answer can be given, for ten years must elapse from the cessation of any particular method of treatment before a patient can be said to be free of all chances of recurrence of the cancer. The pronouncement in your leading article is to be regretted as misleading, and therefore harmful.

Over a week has elapsed, and my letter has not been published, and I am therefore asking you to publish it. I hold the matter to be one of great importance, not merely because the pronouncement is untrue, but because the publishing by lay journals, and particularly a lay journal like the *Times*, of dogmatic statements on matters on which there is no agreement amongst the profession is undesirable and dangerous—I am, etc.,

London W 1 Nov 29th.

VICTOR BONNEY

VOLUNTARY HOSPITAL INCOME

SIR,—In your excellent summary on December 1st (p 1018) of the report of voluntary hospitals in Great Britain (excluding London) for the year 1927, published by the Central Hospital Bureau, there is a citation which, unless given with the full details furnished in the report, may lead to misunderstanding. The summary reads (I give the England figures only, for brevity):

The main sources of income on maintenance account per available bed in 1927 were as follows—Voluntary gifts, £80 75 Receipts for services rendered £29 40 Interest on investments, £18 89 Extraordinary income £18 93

I think any one reading this would suppose that "voluntary gifts" mean subscriptions and donations, or in the words of the Hospital Policy of our Association

'contributions from whatever source to which no such conditions are attached as would involve the obligations of service on the part of the hospital but are charitable contributions to be expended at the discretion of those to whom the management of the hospital is entrusted'

Reference to the original report shows this is not a "Voluntary gifts" includes Subscriptions, £17 32 Donations (including entertainments, etc.), £22 50 Workmen's Contributions, Hospital Saturday Funds, and Contributory Schemes, £36 85 Congregations Collections, £4 08 So that of the "voluntary gifts" nearly one half are contributions for services to be rendered, for there is no doubt that all workmen's contributions of whatever sort are a form of voluntary insurance for hospital treatment, if

and when that may be needed. The report makes this certain, for it reads:

'It will be noticed that where the figures of patients' contributions are high those under the heading of workmen's contributions are low and vice versa. The two columns should be read in conjunction.'

I make no criticism of the manner in which the figures of the report are set out; the text expressly gives the reason for the form of tabulation.

But the distinction I have drawn is of importance in considering the claim of visiting staffs to recognition of their services. Members of staffs discussing the bearing of contributory schemes with their boards should bear in mind that the two sets of figures may be properly presented thus: Subscriptions, donations, congregational collections, £43 90, payments for services rendered or to be rendered, £66 25, and further, that the year 1927 showed an increase under the latter heading, for the figure of the previous year was £60 51.—I am, etc.,

London W 1, Dec. 1st.

N. BISHOP HARMAN.

ETIOLOGY AND TREATMENT OF PAPULAR URTICARIA

SIR,—Referring to my article on urticaria, Dr Burgess (December 1st, p. 1010) takes exception to the following paragraphs:

"Papular urticaria is influenced neither by dieting nor drugs but the patient obtains a respite if he be removed from his own environment."

"There is a curious factor common to all the sufferers: recover immediately they are admitted to hospital, even though no treatment of any description be given. The rash returns after their discharge."

He states that it is likely that others share his disagreement with these statements. This I can readily believe, for at one time I myself imagined that a food protein was the cause of the complaint. I have ventured to forward to Dr Burgess a reprint of a paper published in the *British Journal of Dermatology* (March, 1927), which gives in detail some of the investigations I have made, and on which I base my views. Briefly they are as follows:

In 10 out of my series of 52 cases the eruption commenced whilst the patients were being breast-fed, and weaning did not ameliorate the condition. Two cases were admitted to hospital during an attack, and all their food was brought from their respective homes, nevertheless the eruption disappeared. I have records of over 40 cases admitted during an attack, and in no case did the rash persist, although no treatment was given. Well-known British dermatologists have had the same experience. It has been observed in America (Goldenberg and Rosen, *Archives of Dermatology and Syphilology*, vol. 14, No. 6, p. 698). During this last year 7 cases have been admitted to hospital for the nights only, staying at home during the day, 5 of these were absolutely clear of the rash within one week of this regime, in spite of the fact that they had previously not been free for months. I have records of 6 cases in which the onset of the rash coincided with the patient's removal to a new residence. Finally, Professor Jadassohn of Breslau recently sent me a reprint of an article published in 1902 ('Ueber Prurigo und Neurodermitiden') which draws attention to the fact that in Hebra's prurigo, a chronic eczema closely allied to, and often preceded by, papular urticaria, the rash disappears during the patient's residence in hospital, only to return on their arrival home, and that, in some cases, spending the night only in hospital was sufficient to keep them free of the skin changes.

It is difficult to prove or disprove the theory that the complaint is due to food sensitization, but I submit that there is little scientific evidence in favour of it. The patients eventually acquire a temporary or permanent immunity, yet restriction in diet or an empirical remedy preceding it obtains the credit for the cure.

I do not claim that there is any mythical virtue present in the atmosphere of a hospital, as Dr Burgess supposes, but I believe that an antigen, whether specific or not I do not know, is present in the home of the child and not in the wards of the hospitals in which these experiments have been carried out.—I am, etc.,

Sheffield, Dec. 3rd.

RUPERT HALLAM.

AVULSION OF THE SCALP

SIR,—We should like to congratulate Mr A. Grey Barn's on his exposition in your issue of November 17th (p. 893) of a very successful use of the tubed pedicle flap in the treatment of a case of avulsion of the scalp. We note that all his recent references are taken from the literature of another country. This seems to us rather a pity, seeing that the essential part of the method he employed may be claimed as originating in this country. This means of skin transfer is in regular use by us.

The tubed pedicle was first used in October, 1917, at the Faco and Jaw Hospital, Sidcup, (Gillies, *Plastic Surgery of the Face*, p. 358). On page 379 of Carson's *Modern Operative Surgery* it is stated that "by means of the tubed pedicle, skin may be brought in stages from almost any part of the body to a desired spot." Again, in a paper printed in the *Irish Journal of Medical Science*, February, 1926, one of us wrote, "I have cases in which such a flap has been transferred as far down as the foot and as far up as the crown of the head." Finally, in Ogilvie's *Recent Advances in Surgery* is illustrated a case of avulsion of the scalp in which treatment was commenced on July 25th, 1924, on lines precisely similar to, though more extensive than, those of Mr Barn's case.

Can no good thing come out of Britain?—We are, etc.,

H. D. GILLIES,

T. POMFRET KILNER.

London W 1, Dec. 1st.

HEART SOUNDS

SIR,—Dr G. Arbour Stephens, in his letter on heart sounds of November 17th (p. 916), asks "What authority is there for the suggestion that the thin-walled auricle is capable of producing any sound at all? I have pointed out repeatedly that a muscle when it contracts produces no sound whatever."

The left auricle surely cannot be regarded as a mere contracting muscle, but as the walls of a contracting chamber. Its contents are forced onwards, and if a flow of air can produce a whistle when passing an obstacle, there is no reason why a flow of fluid should not produce a sound.

I cannot understand why Dr Stephens should speak so contemptuously of the thin-walled auricle. Allan Burns pointed out years ago that in a case of calcification of the ventricles the auricle was able to maintain the circulation by itself for a long period of life. The study of cardiology seems to me to have been led into the wilderness by graphic methods for the last twenty years or more, before that time the auricle had a place of importance in the writings of such men as Dickinson, Gardner, Sansom, or Potain.

The thin-walled auricle has the advantage of the stripping David in getting in its throw before the ventricular Goliath starts. The auricle, on contracting, thickens, but—what is of far more importance—its internal area decreases as the square of its diminution in diameter, making the resistance to contraction proportionately less. There consequently comes a point when the auricle can, theoretically, exert a greater pressure on its contents than is ever necessary, and, if resisted, as in mitral stenosis, could overcome the ventricle if it contracted against it, because the intra-ventricular blood pressure is limited in height by the aortic safety valve. In my communication "Dilatation of the heart," in the *British Medical Journal* of February 5th, 1921 (p. 188), I explained this fully.

The "pre-systolic" murmur heard in mitral stenosis is ungravescent in character, and goes up to and into the ventricular systolic time. This is only explicable when it is appreciated that the auricle is physically capable, as it gets smaller, of exerting considerable and increasing pressure on its residual contents. My paper on the pre-systolic murmur, in the *Journal* of January 11th, 1913 (p. 72), dealt with this.

Dr Stephens concludes his letter with a remarkable theory. He writes "I maintain that the normal heart sounds are produced by the movements of this [the pericardial] fluid. If the pericardium be filled with an effusion the movements of the fluid are so restricted that no sound is heard, whilst were the sounds produced by the muscles

or valves of the heart they would be heard all the more plainly, because fluid is such an excellent conductor of sounds."

I do not know where Dr Stophens locates the origin of a vesicular murmur, and breath sounds generally. If he denies that heart sounds originate in the heart because a pericardial effusion causes them to disappear, he must deny that breath sounds originate in the lungs because a pleural effusion also makes them disappear—I am, etc.,

Menton, Nov 21st.

D W SIMMONS

HICKMAN MEMORIAL

SIR,—Your readers will doubtless be familiar with the name of Henry Hill Hickman, the earliest known British experimenter in attempts to produce general anaesthesia by inhalation during surgical operations. Mr C J S Thompson's article in the *British Medical Journal* of April 13th, 1912, deals very fully with Hickman's history, and Dr Dudley Buxton and the Rev Prebendary Joyce have also advocated Hickman's claim to recognition. An Englishman, born at Bromfield in 1800, Hickman practised as a surgeon at Ludlow in his native county of Shropshire, and but for his death at the age of 30 might well have achieved success. His efforts received little or no support, either in England or France. Nevertheless, his experiments in producing anaesthesia, and the idea he pursued with such enthusiasm, fully entitle him to be remembered and recognized.

At the approach of the centenary of his death (April 2nd, 1830) a committee has been formed, with Lord Dawson of Penn as chairman, and Sir StClair Thomson as vice-chairman, to collect funds for the following objects:

1. To renew and suitably inscribe Hickman's tombstone, which is beyond repair.
2. To place a memorial tablet in Bromfield Parish Church.
3. To procure a portrait, to be presented to the Royal Society of Medicine and,
4. If funds permit, to establish a Hickman Prize, or other memorial, for original work in anaesthesia.

The Royal Society of Medicine has given a donation of £10, and members of the Anaesthetic Section (which took the initiative in the matter) have already contributed sixty guineas.

Although Hickman has been recognized, and a "Hickman Meeting" has been held in America, no such honour has yet been paid to his memory by his own countrymen.

Subscriptions, of any amount up to two guineas, may be sent to the Honorary Treasurer, Mr V Warren Low, F.R.C.S., 76, Harley Street, W.1. The envelope should be marked "H. H. H. Memorial."

It is proposed to close this fund by the end of January, when subscribers will be invited to meet and consider the plans submitted by the Organizing Committee, which consists of

Lord Dawson of Penn (Chairman)	Dr H R Spencer
Sir StClair Thomson (Vice-Chairman)	Rev Prebendary W Joyce
The Editor the <i>Lancet</i>	Mr C J S Thompson
The Editor the <i>British Medical Journal</i>	Mr Ashley Daly
Mr V Warren Low	Dr Z Mennell
Dr Dudley Buxton	Dr W J McCaigie (Hon Provincial Sec)
	Dr Cecil Hughes (Hon Sec)

—I am, etc.,

(Signed) **CECIL HUGHES,**
Honorary Secretary

London W.1 Nov 29th

INJECTION TREATMENT OF VARICOCELE

SIR,—Dr Hanschell's excellent letter (November 17th, p 915) on the treatment of varicocele by injection was of great interest. Lest, however, injection treatment be considered a panacea for every type of varicocele (Dr Hanschell does not claim this), a note of warning should be sounded. Varicocele has been treated by injection for some years in France, especially by doctors of the Lyons school. I was surprised, therefore, to find, when attending Siecard's clinic in Paris, that injection treatment for varicocele was not encouraged, and was seldom practised. It was recognized that a certain percentage of cases would yield satisfactory results without excessively painful accom-

paniments, but a number of rather serious and painful ill effects, such as orchitis, hydrocele and extensive inflammation of the spermatic cord, had resulted elsewhere in the experience of those who had treated varicocele extensively by this method, and it was felt, therefore, that the treatment should be advised very conservatively.

That ill results from injection are more liable to occur in this region is only to be expected when one considers the anatomical relations of the injected veins—the pampiniform plexus—and the effects of injection on these veins. The pampiniform plexus lies in a serous sac, and not, as do the veins of the limbs, in the subcutaneous tissue. The veins composing this plexus emerge from the testicle, and with the spermatic plexus of nerves and vas deferens (with all of which the pampiniform plexus is most intimately associated) form the spermatic cord, all being surrounded by serous membrane. Consider what happens to a vein when injected. First the endothelium is inflamed (endothelitis), then all the coats of the vein (venitis), and finally, in a large number of cases, the inflammation spreads to the surrounding tissues (perivenitis). This has been proved experimentally by Jentzer and Askanazy of Geneva, Sicard, and others, as follows. Collargol was added to the sclerosing injection (sodium salicylate), and the mixture was then injected into the veins of several patients, parts of the injected veins were then removed at intervals, varying from an hour to two or three days. The collargol (and therefore the salicylate) was found to have penetrated all the coats of the veins, and even the tissues outside the veins. In the limbs a certain amount of perivenitis is of no serious consequence, since only the skin and subcutaneous tissue are affected, and in the case of haemorrhoids only the mucous and submucous tissue. But when the pampiniform plexus is injected the perivenitis which almost invariably ensues, and which one cannot control, may be a grave matter if excessive, owing to the nature of the perivenous structures—namely, the testicle, serous membrane, and nerves—any or all of which may, and, as reported, not infrequently do, share in the inflammation. Inflammation in the scrotal area makes treatment non-ambulatory. From this it would seem that injection treatment of varicocele should be advocated with more caution than for veins in other areas.

As to the type of varicocele suitable for injection many are of opinion that the selection of any form of radical treatment for this complaint should be governed by symptoms and not by size. If a varicocele does not cause "troublesome" symptoms it is best left alone, a suspensory bandage being worn for support. Should, however, the varicocele be large and make the patient's life uncomfortable, treatment by injection would seem justifiable especially in view of the good results obtained by Dr Hanschell in this type of case. The bad results which have occurred in other hands may have been due to indiscriminate use of injections with perhaps, in many instances, faulty technique. The treatment of any form of varicose condition by injection, whether of the limbs, anal canal, or testicle, is not a simple matter, but requires a skill, both in technique and in selection of suitable cases, which can only be acquired by much practice if consistently good results are to be attained—I am, etc.,

London W.C.1 Nov 24th

P KENNEDY MURPHY M.D.

PREVENTION OF COMPLETE RUPTURE OF THE PERINEUM

SIR,—I have read with interest the article on "The prevention of complete rupture of the perineum," by Dr T Stretthall Wright, on November 24th (p 934). The adoption of prophylactic perineorrhaphy is greatly to be commended, and I have used it with very gratifying results in quite a number of cases. The method I learnt from Professor Blair Bell, who has been teaching it for many years—certainly before the war—but he himself does not claim to have originated the procedure, although he may have done so. In these circumstances I do not think your contributor can claim originality. I may also mention that many lacerations of the perineum can be avoided by adopting Potter's method of "ironing out" the vagina before attempting to deliver with forceps or

perfora version, thus overcoming the muscular spasm and relaxing the perineum

Professor Blain Bell has been in the habit for many years now of measuring the transverse diameter of the pelvic outlet in cases requiring the repair of complete lacerations of the perineum, he has constantly found this to be so narrowed that the head must have been forced further back than normal in the process of delivery and the perineum inevitably and completely lacerated—I am, etc.,

Liverpool Nov. 29th

M. M. DAWSON

PAINLESS LABOURS

SIR.—In view of Dr. Mary DeGaris's article of October 27th (p. 745) the following case is of interest

I was called at 10 a.m. on November 13th to see a woman whom I had undertaken to attend during her confinement. She was aged 36 years, perfectly healthy, and had had two previous confinements.

I found her up and performing her household duties. She said that she had no pains but thought she was in labour as water had been coming in little gushes since 8 o'clock. Vaginal examination revealed that the os was about half dilated and the head well down in the pelvis. I saw her again about 3 p.m., she had had no pains in the interval. She sent for me about midnight, and on my arrival I found the head crowned almost immediately she gave birth to a male child weighing 7½ lb. The placenta followed in five minutes, and there was scarcely any haemorrhage. She had no pain whatever during the day and only three pains as the child was being born. The puerperium has so far been normal, her temperature has never been above 98.4° F.

The history of her first confinement at the age of 24 years is similarly painless. On getting out of bed in the morning there was a gush of water and she felt something was going to happen. She had one pain and the baby was born before the doctor or nurse could be summoned. After second confinement, when 32 years old, lasted eighteen hours and was associated with a good deal of pain, there was difficulty in delivering the placenta—I am, etc.,

W. A. MURPHY, M.B., B.Ch. Dub.

March, Cambs, Nov. 17th.

"THE RIGHT TO PRACTISE"

SIR.—The sentence quoted by Mr. W. L. Hempsen in his letter published in the Journal of December 1st (p. 1011) under the heading of "The right to practise" was spoken in reference to qualified medical practice.

I think it was abundantly clear to my audience that anyone could carry on "unqualified practice," but that the inclusion of the name in the *Medical Register*, and not degrees or diplomas, gave the right to qualified medical practice, and that the Medical Act of 1858 was introduced so that (in the words of the Act) "persons requiring medical aid should be enabled to distinguish qualified from unqualified practitioners."

I am very grateful to Mr. Hempsen for making this point still more clear. It is nice to see that he still takes an interest in medical affairs—I am, etc.,

Hyde Dec. 1st.

J. GORDON MACQUEEN

TETANY INVOLVING THE RECTUS ABDOMINIS

SIR.—I was much interested to read the letter on this subject by Surgeon Commander H. Hill, R.N., in the *British Medical Journal* of November 17th (p. 916). Surely the condition he refers to must be well known to those who put a heavy strain on the rectus abdominis.

Many years ago, when I was training for Henley regatta in one of the senior eights of the London Rowing Club, I was reluctantly obliged to give up my seat in the boat from the above cause, after having gone through most of the training required, this was one of my greatest disappointments in life. I have had a few attacks of this variety of cramp since, but only after riding a pulling horse. During the past seven years I have been in constant attendance in the riding school of the Royal Horse Artillery, and have encountered quite a number of such cases. Sometimes I have been in time to feel the hard lump, sometimes it had subsided before I examined the patient, but the history was generally the same—"Came on after going over the jumps", it was always the rectus

abdominis which was affected, and generally the top part of the muscle.

Of course I have had riders complaining of cramp in other muscles, such as the hamstrings, calves, and adductor magnus, but not at the same time as the rectus. Some years ago Professor William Rose, then professor of surgery at King's College Hospital, gave me this remarkable advice: "Hold a piece of stick sulphur in each hand during the attack, and soon the pain goes and the muscles relax." I have seen this act like magic in severe attacks of cramp and have tried it myself, sometimes it takes longer to act than at other times. Professor Rose gave no explanation how the sulphur acts, but it possibly sets up some kind of electrical action.

I may mention that most of the cases of cramp in the rectus abdominis I have met with have been in recruits learning to ride and in those who ride more by grip than by balance. The hunting men (the officers) never seem to get it—I am, etc.,

B. W. LANCHESTER, Lieut. Colonel R.A.M.C.,

Medical Officer in Charge Royal Horse Artillery
Trenbridge Wilt.

SO-CALLED TITANIUM RAYS

SIR.—In my "Notes on titanium rays" I explained that "titanium rays are obtained from electrodes containing from 1 per cent to 5 per cent of the rare metal titanium and 95 per cent or more of wolfram." I also stated that "for many years I made a special study of tungsten rays and used them exclusively. In the latter part of 1924 I began to observe the effects of titanium rays, and the results led me to adopt them."

This simple statement of fact apparently does not please your correspondent Dr. Heald (November 24th, p. 962). He thinks we should word it differently, and proceeds to give a paraphrase which, in his opinion, correctly expresses "the more generally accepted terms of physics." Unfortunately there happens to be no physical terms in which we can express ourselves about what we at present call "ultra violet rays," because we know nothing about their physical action. At present we only have clinical experience to guide us, and the less we wrap up our ignorance in pseudo-scientific phraseology the more likely we are to get at the truth. We have learned that physical differences exist in the rays according to the manner in which they are produced, and that this involves a difference in technique, thus we can irradiate the whole body with a single mercury-vapour lamp, or, by my method of using titanium rays, with a battery of twelve arcs. We should not use this very expensive method unless the results justified it. We have lately made some experiments on the preventive powers of the rays in question. We used a fresh cow hide 5/16 in thick, this was placed over the lens of the camera, on which the rays were focused at varying distances. The results indicated active penetration, an interesting feature being that there was apparently little difference between two and four minute exposures. We do not know of any experiments with which to compare these, so cannot say that the unexpected penetrative powers were due to the titanium in the electrode—I am, etc.,

Bath Dec. 3rd

ARTHUR ROBERTS, F.R.C.S. Ed.

THE JEWISH PATIENT

SIR.—I have unfortunately not yet read Dr. Hutchison's remarks at the Royal Society of Medicine on October 23rd, concerning the Jewish patient, but I should like to endorse the view expressed by Dr. L. S. Woolf in your issue of November 17th (p. 916).

I have been a resident at the London Jewish Hospital (where about 75 per cent of the patients are Jews), at the Manchester Jewish Hospital (where about 25 per cent of the patients are Jews), in addition to such institutions as the Worcester General Infirmary, where I did not see a single Jewish patient over a period of fifteen months, and thus perhaps I may be considered qualified to speak on the subject.

In my experience the Jewish hospital patient is the most difficult and trying of patients. His lack of control, his

over anxiety, his readiness to fly for half a dozen opinions at the same time, and his occasional insolence are often a source of exasperation to his medical attendant.

But I do consider that only a very small part in the causation of these characteristics is played by the racial factor. In fact, the care bestowed by the Jewish parents on their children (were it only moderated), and the tendency of the Jewish patient to seek the advice of a medical man in the early stages of disease, are a matter for encouragement rather than condemnation. The chief cause is undoubtedly the foreign upbringing, for a very large proportion of the East End Jewish hospital patients are of foreign birth, and their children, even if born in England, are brought up in an essentially foreign home atmosphere. In Manchester, where the foreign element amongst the Jewish patients is not so pronounced, we find the difficulties not nearly so well marked—I am, etc.,

G. GREGORY KAYNE, M.D., M.R.C.P. Lond.

Manchester Nov. 17th.

MEDICAL PRACTICE FOR WOMEN IN PALESTINE

SIR,—In the *Journal* of October 6th (p. 624) there is a report of an address by Dr. Andrew Balfour on the possibilities of the tropical field for medical women, in which he mentions Palestine as one of those countries where medical women should find openings. The following facts give a picture of conditions prevailing at present, and as they will probably remain for a long time to come.

There are in Palestine (the figures are those for January 1st, 1928) 634 doctors licensed to practise of whom 104 are women. The population is roughly 750,000 (excluding about 100,000 nomads who need not here be considered), of whom one may count about 500,000 as living under primitive conditions and not accustomed to consult a doctor except in extreme cases. So much for general practice. As to infant welfare centres, it is true that there are 31 in the country, but of these 20 have been established by Jewish organizations and are fully staffed, only 8 are under Government control.

The reply given by Mr. Amory in the House of Commons, as reported in the *Journal* of May 5th last (p. 778), lamentable though its first part is, is sufficient warning to any woman doctor looking to Palestine to provide openings for practice (outside the medical missionary field). Mr. Amory said "that as yet no Government medical appointments in Palestine were open to women doctors. The special positions for dealing with infant welfare which ordinarily were filled by women doctors were covered in Palestine with a widespread service of nurses and midwives. In the opinion of the Government there was no special opening in Palestine for women doctors in other capacities"—I am, etc.,

Tel Aviv Palestine Oct. 25th.

ANNIE FOXER

BOOKS AS FOMITES

SIR,—The brief statement on this subject in the report of the consultative committee of the Board of Education on books in public schools, to which attention was called on November 24th (p. 951) does not give any details of the recent work on the subject which has been devoted to the recovery of the specific streptococcus from fomites in cases of scarlet fever. Thus Friedemann and Deicher found the scarlet fever streptococcus in the walls, beds, curtains, and other objects in the sick room of scarlet fever patients, and came to the conclusion that then results "underline the necessity of a thorough final disinfection of the sick-room in a case of scarlet fever." Balmain found that in experimentally infected books the *Streptococcus scarlatinae* could survive for eighteen days even in lightly infected books. Feigin confirmed the latter's results. He also investigated books naturally infected with scarlatinal streptococci, and his conclusion was that "books handled by scarlet fever patients harbour the germs and are capable of contributing to the spread of scarlet fever. It is necessary to avoid all contact with these books for at least six weeks, and even after this period it would be best to disinfect them."

¹ *Deut. med. Woch.* 1926 No. 51.

² *Lancet*, 1927 II 1128.

³ *C. R. Soc. de Biologie* 1928.

Again, it was discovered by the Pathological Laboratory of the Ministry of Health* that "in books used by three children out of fifteen who sickened with scarlatina, hemolytic streptococci were found. Books used by twelve children who developed diphtheria were also examined. In one instance virulent diphtheria bacilli were isolated."

It is impossible to prove that fomites spread such an endemic disease as scarlet fever, but at present the safest conclusion would be that stated at the discussion on the subject by the Society of Medical Officers of Health—that in the light of uncertainty definite measures should still be taken to prevent the possibility of the spread of infection by this means.

The legal position of a library which issued books which had been in the possession of scarlet fever patients would be an invidious one, if no precautions had been taken—I am, etc.,

A. H. G. BURTON,

Medical Officer of Health, Borough of Ilford.

November 27th.

"HYPERVITAMINOSIS"

SIR,—The letter of Dr. Leslie J. Harris in your issue of November 24th (p. 964) lays down several conclusions to be drawn from the data available. The weight of authority naturally attached to Dr. Harris's statements by your readers impels us to ask for space to make the following comments on two of his conclusions.

No. 6 states that since various specimens of irradiated ergosterol may vary in antirachitic activity, it is desirable that they should be subjected to physiological assay before being issued. In regard to this statement, we should like to point out that our products containing irradiated ergosterol are subjected to physiological assay before being issued, their activity being expressed in terms of the unit described by Dr. K. H. Coward.

No. 7 states. It is conceivable that different specimens, irradiated by different methods, may contain varying amounts of any toxic by-product the optimum manufacturing procedure needs to be worked out. The British Drug Houses have long since determined the practical optimum manufacturing procedure. The method arrived at has only been obtained after numerous experiments, in which fullest use was made of physiological tests.

—I am, etc.,

CHARLES ALEX. HILL,

London N., Nov. 27th.

Managing Director British Drug Houses Ltd.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week read the Local Government (Scotland) Bill a second time after a two days debate. The Consultative Health and Housing Committee arranged to meet on December 5th, under the chairmanship of Dr. Fremantle, to hear Sir Kingsley Wood speak on points raised during last week's debate on the Local Government Bill. The special committee of the British Medical Association has accepted the invitation to discuss medical aspects of the same bill with the Parliamentary Medical Committee on December 11th. Certain medical and other members interested in voluntary health associations are discussing with those associations how, accepting the decision of the House of Commons in favour of the block grant and of the general lines of the bill, amendments can be suggested to protect the interests of voluntary associations.

On December 4th Miss Bondfield introduced a bill to enable local authorities to provide footwear for children in distressed areas. The bill, she said, was brought forward by the seven women members of the House, irrespective of party. The bill was read the first time.

Local Government Bill.

The Local Government Bill was read a second time in the House of Commons on November 28th after an amendment for its rejection had been defeated by 344 to 165. In the debate which preceded—part of which was reported in our last issue—Dr. Fremantle was followed by Colonel Wedgwood, Colonel Ashley, and Miss Susan Lawrence.

Mr. PERCIVAL LAWRENCE said that at present the system was that the Minister of Health increased the grant for maternity and child welfare services only when those services were increased subject to his approval. The bill would encourage local authorities to spend little on these services. To the extent by which a local authority refrained from keeping pace with the country

* Chief Medical Officer's Report 1928.

as a whole it would have more money from the Exchequer grant available in relief of its own rates. It was true that in exceptional cases the Minister had power under Clause 86 to drive hopeless lagging authorities but that would only apply to those which had fallen right out of the ranks.

Dr. VERKOV DAVIES intervened to point out that Clause 86 postulated a reasonable standard of efficiency.

Mr. PRINCE LANREVE said that action was only contemplated where the health of the inhabitants had been, or was likely to be, endangered by the neglect of the council. He contended that the clause was obviously exceptional; he hoped that the Minister would find it possible to take maternity and child welfare services out of the block grant system. He drew attention to the provision in Clause 13 making it obligatory to raise from patients or their relatives the money expended on their behalf in maternity houses. If persons suffered from infectious disease or venereal disease they were, however, to be treated free. Any step which would make it less easy or less advantageous to extend the maternity service, and would make it more difficult for persons to avail themselves of this service, was to be deplored.

Lady ASTOR said she hoped later to move an amendment to keep the maternity and child welfare services on a percentage basis for the first five years and to specify that after that period the Minister ought to consider the adequacy of the maternity services when deciding whether he ought to reduce the block grant to any authority. She remarked that if the block grant were introduced a guarantee was needed that money would be spent on increasing the maternity services. Not the local authorities but the central authority had pressed for them and they should continue to be subject to some stimulus from the central authority. The new infant welfare centres had not cost the country a great deal. Ten years ago the Treasury grant amounted to about £200,000 and ten years had passed before that grant had increased to about £800,000. Since 1915 when the services were started infant mortality had been reduced from 110 per 1,000 to 70 per 1,000 and the reduction was continuing steadily. The tragedy was that maternal mortality had been stationary for the last twenty years. They should have more ante-natal clinics, more maternity homes, more beds in hospitals, and extended midwifery services.

Mr. SIMPLY WEBB said the block grant was to be based on relative needs as measured by obligatory services. Maternity and child welfare were not reckoned as a need. Under this scheme the same grant would go to the district that did practically nothing for maternity and child welfare as to the district that did its duty. Mr. Chamberlain had said that he intended to keep the backward places up to the mark. That sentiment had gained the adhesion of Dr. Fremantle who was so keen on public health but the bill did not say that. Clause 51 on which the Minister relied, limited his right of survey to the area of infectious disease, and left out maternity and child welfare altogether. In Clause 4 the words 'public health' did not include tuberculosis, which was there put in separately. Lawyers would construe from that that public health was something which was independent of maternity and child welfare. Yet the percentage grants had been instituted to encourage these optional services and the report of Sir George Newman, issued a few weeks ago had said that there can be no doubt that the percentage of Exchequer grants in aid of health had been of the highest possible value and incentive during the last fifteen years in getting special medical services in operation and in guiding their direction.

Sir KINGSLEY WOOD protested that the whole of the quotation from the Chief Medical Officer would bear a different construction.

Mr. WEBB said he had not misstated Sir George Newman's strong opinion which was well known to Dr. Fremantle and to other members who took an interest in health services. There was no adequate provision in the bill to prevent positive backwardness in these optional services. These new services were not yet general over the kingdom; there were only 1,695 infant centres in the whole of the kingdom. Could they ask a poor mother to travel more than a mile with an infant for examination and weighing and so forth and to attend regularly? How many of these infant centres would be required to cover the 58,000 square miles of England and Wales?

Mr. CHAMBERLAIN asked whether Mr. Webb contended that maternity and child welfare service was not public health.

Mr. WEBB replied that if the Minister mentioned one term in a series and did not mention others he might be taken deliberately to have omitted the others. The Minister should name the optional services after the words 'public health' in Clause 86 and instead of the words 'reasonable standard of efficiency' should use 'reasonable standard of adequacy and efficiency'. In some backward counties maternity and child welfare schemes were efficient but not adequate. Five years hence the maternity and child welfare service ought to have reached twice its present standard of adequacy but Mr. Chamberlain had taken no steps to secure that. The bill provided in Clause 13 that the 'average daily cost' of maintaining a person in a hospital under the bill could be recoverable from the patient. If the hospital was nearly empty the cost per patient would be enormous. Mr. Chamberlain had just authorized the Metropolitan Asylums Board to equip an expensive ward and to provide it with radiums at an enormous cost for eight women only. The average for each of these per day would be a very large sum. A hospital at Edmonton had just received power to spend £8,000 on radium for a very small ward.

Mr. CHAMBERLAIN intervened to say that the cost of treatment must be separated from the cost of maintenance. The patient would not be charged with the cost of treatment.

Mr. WEBB quoted the clause as saying 'maintenance and treatment'. He remarked that Mr. Chamberlain had been paying regard to the susceptibilities of the voluntary hospitals. He

imagined these were afraid that public health institutions would be so good that people would not want to go to voluntary hospitals. The charge for treatment in public health institutions was to be made in every case except for infectious disease. It had been expressly ordered that 'infectious disease should be granted, as of right to everyone absolutely free'. Women suffering from venereal diseases were treated specially at certain maternity and child welfare centres, and had to be treated free, yet other women were to be charged at these centres.

Mr. J. PALM supported the plea that the percentage grant should be continued for maternity and child welfare services. Bradford had just closed a school for blind children. Six years ago it had a hundred or more in the school. To-day only six required attention. As a result of infant welfare work eliminating ophthalmic neonatorum there was little blindness now. Condemning Clause 13, regarding the charging of costs of patients under the Poor Law, Mr. Palm said that powers similar to those given under Section 132 of the Public Health Act, 1875 and Section 58 of the Bradford Corporation Act 1925 would give local authorities all that was necessary to prevent imposition. The municipal hospital of Bradford cost £100,000 last year, but the total recovered from patients was £6,391. In concluding Mr. Palm said he must pay tribute to the advice received from time to time from the medical men in the service of the Ministry of Health.

Captain GUYSTON said he lived in a village in Gloucestershire and was often asked to get persons into hospital. He invariably found that the hospitals were full and that there was a long waiting list, yet in many Poor Law infirmaries beds were available. The right thing to do was to make these institutions available, and, if necessary, to turn them into specialized hospitals. They had to get the people to look upon these infirmaries as the proper hospitals of the poor of the country and a small charge would be one way of getting rid of the taint of pauperism. He was grateful that the bill dealt with the registration of births, marriages, and deaths a subject on which he had introduced a bill last session.

Mr. LANSHURY quoted from the report of the Chief Medical Officer to show that some definite adjustment would be needed to secure the special health services under a block grant system. The bill Mr. Lansbury remarked would not make a definite allotment for maternity and child welfare services. Mr. Chamberlain had already cut down the assistance to maternity and child welfare centres.

Sir KINGSLEY WOOD said the bill was a most important contribution to local government reform. It would be impossible for any Government to make it mandatory upon the local authorities to break up the Poor Law. As an illustration of that he gave the case of the mental deficient who if the Poor Law were broken up, would go to the local authorities and be treated exactly as others who were similarly circumstanced. It would be impossible to carry that out owing to the great lack of accommodation at present, a lack entailing great capital expenditure which would, he hoped, be minimized by the bill. The present percentage grant system was irrational and unjust especially for the health services. Merthyr Tydvil had rates of 27s. 2d in the £ with 105 children under 5 years of age per 1,000 of population. Southport with about the same population, had rates of 8s. 4d in the £ with 62 children under 5 per 1,000 of the population. Merthyr got £1,500 a year for its grant aided health services and Southport £8,000. Gateshead, with 14,000 children and South Shields, with 13,000 children, each received a grant of £1,600 for maternity and child welfare services. Bournemouth with 5,300 children, and Eastbourne with 2,976 children received £2,900 and £2,700 respectively. The Government was now spending £178,000 on maternity and child welfare services. Clause 86 was designed to give the Minister power to say to a local authority, 'You have got to get on with your maternity and child welfare services'. If they did not then do so within a reasonable time they could be penalized in their grants. There need be no apprehension that people would be confronted with heavy hospital charges under Clause 13, in which the system of the voluntary hospitals was followed.

As stated above, the amendment for rejection was then defeated by 344 to 165 and the bill was read a second time. A financial resolution authorizing the expenditure made necessary by the bill was carried during the following sitting on November 28th. On this resolution Dr. VERKOV DAVIES put a case for the urban district councils. He also pointed out that the British Social Hygiene Council which now received a grant from the State would get none under the bill. They would depend on grants from county councils and local authorities, which had not seemed anxious to spend money in this direction. He hoped the council would be better treated as that would be a great benefit to the health services. He favoured the block grant for health services. The percentage grant had been a stimulus to local authorities to start these services, but the experiment had lasted long enough. All the authorities which were anxious or willing to avail themselves of these services had done so. The block grants would be in the hands of the county councils, through whom a large number of welfare centres were now worked. The county councils would have more money than before and there would be a larger number of welfare centres throughout the country and a good general standard of efficiency.

In moving an amendment challenging the proposed system of block grants, Mr. SCOTT said the Association of Infant Welfare and Maternity Centres had passed a resolution against this proposal as not making adequate allowance for expansion in the next five years. The amendment was defeated by 285 to 122, and the financial resolution was carried by 280 to 132.

In a reply to Dr. Fremantle, on November 28th Sir KINGSLEY WOOD said that wards for the sick and infirm in the separate

infirmaries of London which were ordinarily staffed by trained nurses probationers in various stages of training, and ward maids or attendants contained 16 520 beds. Wards for the sick and infirm included in other Poor Law institutions were usually staffed by trained nurses, assistant nurses, and attendants, and contained some thousands of beds. No precise figures were available of the number of beds in wards served by untrained attendants in the Poor Law institutions of London, nor of the numbers of trained nurses and untrained attendants respectively in these institutions.

On November 28th Sir KINGSLEY WOOD told Lady Astor that it would not be necessary during the next financial year to reduce the grants available for certain local authorities in aid of their expenditure on milk. A reduction of £12,000 made in the current year was purely temporary, to keep the grants paid for the health services within the amount voted by Parliament.

On December 3rd, Sir KINGSLEY WOOD told Viscount Sandon that local authorities would have power, except in cases of infectious disease, to recover from the non-destitute expenses for treatment in their hospitals as well as for maintenance, to the extent of the average daily expenditure of the hospital on treatment, but not by reference to the actual cost of the treatment of the particular patient.

Local Government (Scotland) Bill

On December 3rd, Sir J. GILMOUR moved the second reading of the Local Government (Scotland) Bill, which in the main, seeks to achieve in Scotland similar objects to those aimed at by the Local Government Bill in England. He said that larger units of local government were required, particularly in view of the de-rating proposals. There were glaring inequalities and differences in the burdens which local authorities had to bear, 77 per cent. of the present pauperism in Scotland was in thirty-seven parishes in the larger burghs and 23 per cent. was scattered over 832 parishes. In the larger parishes the cost of administration was about 3 per cent. while in many parishes it was 18 or 20 per cent. of the amount spent in relief. The small authorities were obviously unable of themselves to supply adequate and up-to-date hospital accommodation. The first part of the bill dealt with local government administration. The services affected by the changes proposed included the Poor Law, the major public health services among which were hospitals and town planning. It was proposed to set up new authorities as units of administration consisting of the counties and the boroughs with a population of 20,000 and over. The parish councils would be abolished. The administration of poor relief by far the most important function of the parish councils was to be transferred to the county. For the purposes of the bill the small burghs were those with a population of under 20,000 and certain of their functions would be transferred to the county councils. These functions would include the major health services (including infectious disease and maternity and child welfare) milk and dairies adulteration of food and drugs unsound food and town planning. The total amount of rate loss due to de-rating was estimated in Scotland to amount to £3,200,000 a year. The total cost to the Exchequer in each of the first five years was estimated at £4,125,000. The total extra revenue to local authorities in each of the first five years—new money—was £322,000. The same guarantees were being given in Scotland as in England, and the effect broadly of the guarantees would be that in the first quinquennium only three counties out of the thirty-three would require an additional grant to bring the gain up to 1s. per head to compensate them for the loss of rate and grant. No large burghs would require an additional grant, the amount of the gain in every case being in excess of 1s. per head. The new money being distributed (£322,000) represented a sum of 3s. 9d. per head of the population, and it was estimated to be equal to a rate of 6d. in the £ on the reduced rateable valuation of Scotland. Of the smaller burghs 115 or 84 per cent. would have their rates reduced and of the 869 parishes 585 or 67 per cent., would have their rates reduced. It was calculated that every industrial area would gain and in addition, seven out of every eight persons would gain.

Mr. JONASTON moved the rejection of the bill.

Dr. DRUMMOND SMITH strongly opposed the bill which he said presented great dangers to the public health services in Scotland. The block grant would adversely affect these services, which were rapidly developing. Speaking of the way in which the child welfare scheme had extended he said that in Edinburgh, in 1917, when it was first started the net expenditure was £35,000. In 1920 before the amalgamation with Leith took place the expenditure was up to £85,000 and now in the larger area, the amount was £115,000 of health expenditure as compared with £35,000 only eleven years ago. This development was also only the beginning of a larger service in view of the problems facing local authorities to-day. For instance, the question of the rheumatic child had been tackled by the London County Council and also by Birmingham. Another very important service was that of the treatment of crippled children 75 per cent. of whom could be made self-supporting if they were properly treated in the earlier years. There was the question of mental deficiencies in regard to which public opinion was now being roused. To give special education to mental deficient up to the age of 16 and then to throw them out without any further public supervision, unless in the case of certifiable persons was simply to invite disaster both to them and to the community. Then there was the subject of cancer. Something might be discovered at any moment in connexion with cancer and it was now being realized that supplies of radium which were very expensive were essential in the treatment of this problem. Child welfare and maternity work was ripe for a very big advance and public opinion was ripe

for that advance. There had been a great deal of talk about maternal mortality. Dr. Findlay, the child welfare officer of Edinburgh had pointed out that in 1927 in Edinburgh the figures of the maternal death rate among mothers who had no ante-natal attention were 11.2 per 1,000 conceptions while in the ante-natal clinics they were only 2.4. The total figures were not large enough for the actual scientific determination of these proportions but it was plain as Dr. Findlay said, that the ante-natal clinics very definitely assisted in lessening the maternal death rate. There had not been enough of this work to cover the field either in Edinburgh or elsewhere in this year. This year was the standard year, and it was going to determine the relative proportion of money to be given in the grants for the next five years. Therefore, if the extension of this service was proposed in Edinburgh and other places—there were already schemes for homes and for other things to deal with these cases—the persons responsible for the finances would say, "No, we cannot go on with that now. We have got our grant on the basis of this year's expenditure. We must wait until the fourth year, until the next standard year comes along." That was not a satisfactory position for the health services. It seemed to him that the 6d., which the Secretary for Scotland had said was going to be saved in rates or given as a present by this bill would very soon be wiped out by the inevitable increases in expenditure which would result from the normal development after this year, and which would have to be met on a very narrow rating basis, and would certainly cause an increase in the rate. The same thing applied in regard to venereal disease. At present the State paid 75 per cent. and the local authority 25 per cent. Now the local authority would pay the whole 100 per cent., and while it was likely that large cities like Edinburgh would maintain their service there would be no stimulus to those backward areas which had never provided any efficient venereal disease service, to pass the standard year, and to go forward and impose on their own ratepayers the charge for the necessary extension of those services. The Government had taken a very wrong line in regard to what the Edinburgh authorities put forward for compulsory treatment in venereal disease. They turned that down. At the same time in this bill they had cut out the grant for propaganda. If the voluntary system was to be successful in venereal disease propaganda was absolutely essential and propaganda must be national, because voluntary contributions had been tried before and had been entirely unsuccessful. Such things as films and various items could not be supplied by individual authorities but must be done nationally. This had all been cut out by this bill. Some people had said that they looked forward to this bill as a great help to public health. He wished he could think so. He would be delighted to support it if he thought so. He thought that it was a backward measure, and that it was going to be a terrible danger to public health. The public health service was not going to be maintained, and if it was it would only be by the sacrifice of local authorities in rating their own people rather than let the services suffer.

As to hospitals, he would like certain information on a point which had never been cleared up. Under this bill the town councils were going to take over institutions such as the large hospitals in the cities, which at present were run by the parish councils. There were two hospitals in Edinburgh—Craiglockhart and Craigleith. It was proposed that all the poor people should be taken from Craiglockhart and kept in Craigleith which had been restored to them after the war pensioners had been using it. Craiglockhart ought to be used as an overflow for the Edinburgh Royal Infirmary, which had a waiting list of over 2,000 with many urgent cases wanting to get in. What was to be the position? Was it the case that Edinburgh Town Council would only be able to treat in that hospital necessitous poor, and would Edinburgh be compelled to get back from the relatives of these people so treated any sum expended on their maintenance? That was a very important point. In Aberdeen at present there was a working arrangement and the parish council hospitals had been handed over to the Public Health Committee of the town council, and were being worked by them. In Glasgow there was a working arrangement with Stobhill, one of the finest fitted up hospitals in the country. What was going to be the new position if the present arrangement did not involve any Poor Law system in the working of these hospitals by the public health authorities? Did the new proposals compel the town council to treat the people in those hospitals—if they were intending to use them as general hospitals—differently from the people in the tuberculous hospitals?

Another point of some importance was that one of the advantages of the new proposal was that these new institutions which were taken over were going to be brought up to date. Many of the Poor Law institutions were out of date and badly equipped. Who was going to pay for bringing them up to the proper standard of equipment? Certain people were so keenly wedded to the voluntary system that they would rather see people suffering and deprived of medical assistance than impose on that system at all. He hoped that no considerations of that kind would prevent every facility being given and every accommodation being taken advantage of for the medical services of the people who required it. He thought there would be opposition from those people who believed that a well-equipped and well-run municipal hospital would tend to damage the voluntary hospitals of the district. He believed however that for many years there would be plenty of room for both of them and he hoped that the municipal authorities would be encouraged to use these institutions to the utmost of their capacity. He would like to know, in passing, what was going to happen to the Highlands and Islands Medical Fund. He opposed the bill which instead of being for the Government a lifeboat would prove to be a millstone.

Dr. ELLIOT Under Secretary for Scotland replying to the debate, said the scheme had been fully discussed in Scotland especially by the municipality of Glasgow and there was no

suggestion of party opposition to the measure on the part of the Socialist members of the Glasgow corporation. Proposals were included in the bill to secure that there should be working-class representation on the new bodies to be set up. Committee after committee had reported in favour of the transference of the health services from the education authority to the single health authority. He gave instances of needless duplication of clinics for children under the present authorities in Glasgow. The bill would put the five great semi-national services of Scotland—the roads, health, education, Poor Law and police services—on the widest possible basis.

The amendment was rejected by 319 votes to 150 and the bill read the second time. It was afterwards sent to committee of the whole House instead of to the Standing Committee on Scottish bills.

Sir J. GILMORE stated on December 4th in reply to Mr. E. BROWN that there were 307 public health local authorities in Scotland all of whom had powers under subsection (1) (b) of Section 3 of the Notification of Births (Extension) Act 1915 subject to the approval of the Scottish Board of Health to make arrangements for attending to the health of expectant and nursing mothers, and of children under 5 years of age. The number that had made such provision up to date was 243.

Women Medical Students

Mr. A. M. SAMUEL told Mr. Rhys DAVIES on November 22nd, that he had no information of the number of entries of women medical students in England, Scotland and Wales for the last five years. Returns made to the University Grants Committee showed that the total numbers of full-time women medical students attending university institutions in the past five years were

	1923-24	1924-25	1925-26	1926-27	1927-28
England	1,375	1,197	1,059	930	862
Wales ..	35	32	30	32	30
Scotland ..	610	431	315	274	254
Total ..	2,020	1,660	1,402	1,236	1,146

Admission of Voluntary Boarders to Public Asylums.—In the House of Lords, on December 4th Lord SAVONTER asked if the Government would in the present session introduce legislation to enable voluntary boarders to be received into public asylums. The Earl of Cranbrook urged that such legislation would be in the interests of the medical profession. Doctors would be able to study these cases in their early stages and the treatment of mental disorder would be linked up with general practice in a way not possible at present. The Earl of Onslow said there were difficulties in dealing with the recommendations of the Royal Commission on Lunacy separately. It was impossible to introduce a comprehensive bill this session but the Government hoped to deal with the whole subject of lunacy and mental disorder. Provision for the admission of voluntary boarders into public asylums would find a place in the measure.

Silicosis.—Commodore KIXO, answering Mr. D. Greenfell on November 28th said silicosis was not a notifiable disease. There were no statistics of disablement from the disease but the general evidence was that it was comparatively rare among miners. He had no evidence of an increase in the number of cases. Preventive measures such as improved ventilation and the use of water or of a mechanical dust abstracter were necessary when drilling was done in highly siliceous rock and the Government inspectors were attending to this. On December 4th Mr. REXFORD SMITH asked the Home Secretary when the inquiry of his department into silicosis was likely to conclude and if he proposed to publish a White Paper on the subject. Sir W. JOYNSON HICKS replied that if as he supposed Mr. Smith was referring to the proposed medical inquiry to consider the arrangements for diagnosis of silicosis, that inquiry had only just been set on foot and he could not forecast the time it was likely to take. If however, Mr. Smith was referring to the draft scheme of compensation which he was about to make for silicosis in various industries that would be issued very shortly and laid before Parliament. No other publication was contemplated.

Dangerous Drugs.—Sir VIVIAN HENDERSON, answering Colonel Vaughan Morgan on November 22nd said the alkaloid codeine had not been added to the schedule under the Dangerous Drugs Act. Codeine was not regarded by most authorities as a habit-forming drug and was not included in the International Conventions of The Hague and Geneva. On November 26th Earl WINTERTON told Lieut. Colonel Vaughan Morgan that various alkaloids of opium had been manufactured at the Glaxupur factory from waste products and contraband opium for many years but it was not until about 1924 that they began to find a market in substantial quantities outside India. They were exported to the United Kingdom only where their disposal for strictly medical and scientific purposes was governed by the stringent provisions of the Dangerous Drugs Act. In a reply to Mr. Wellock on November 25th Sir WILLIAM JOYNSON-HICKS said that for the past four years raw opium and crude morphine had been imported into this country from India for manufacturing drugs replacing to a considerable extent opium imported from other countries. He could not give an assurance that there would

not be an increase in the import of medical opium or of alkaloids, as the amount of opium required for medical and scientific purposes fluctuated from year to year. The trade was carefully supervised and there had been a progressive decrease in the amounts imported in recent years.

Immunity against Diphtheria.—Mr. CHAMBERLAIN stated that many of the metropolitan borough councils had undertaken with the sanction of the Ministry of Health, immunization against diphtheria by the Schick test. The London County Council did not directly participate in this work but as local education authority it assisted, when requested, by disseminating information on the subject through the schools.

Maternity Services in Scotland.—Sir J. GILMORE, replying to Mr. Johnston on November 27th said that while in the opinion of the Scottish Board of Health every area in Scotland would benefit by the adoption of a maternity service and child welfare scheme providing as a minimum for the services of a medical officer and a health visitor there were many areas where the provision of a centre was impracticable.

Testing of Samples under the Food and Drugs Act.—On November 26th Sir KINGSLEY WOOD replying to Mr. Verron DAVIES stated that informal testing of samples under the Sale of Food and Drugs Act was designed to obtain information for administrative purposes. The Minister of Health was not satisfied that the publication of statistics combining the results of formal and informal tests would accurately reflect the amount of adulteration in any district. The Minister would, however, consider his suggestion.

Admissions to Mental Institutions.—During the year 1927 the admissions to county and borough mental hospitals in England and Wales numbered 20,474 and there were 1,419 persons admitted to other institutions for the care of the insane or committed to private single care. The total of 21,893 compares with 21,924 in 1926 and 21,784 in 1925.

Tuberculosis in the Army.—Answering questions by Mr. More-Bathia on November 28th Colonel HEADLAM said it was impracticable to set out the new rules and principles governing attributability of tuberculosis cases in the army. The value of working rules of this kind depended on the power to apply the spirit of them to the facts of individual cases as disclosed by the medical evidence. All claims would be considered in the light of the new rules which were much more favourable than the old ones. October 31st had been taken as the date for the introduction of these rules and the Admiralty did not propose to depart from it. The Admiralty could always go back behind a date for medical reasons and any case would be considered when it came up. He could not say whether the rules would again be revised when the Joint Committee of the three services reported. Mr. VERRON DAVIES asked whether a certificate from a medical man which pointed out that a discharged sailor was suffering from tuberculosis attributable to the conditions of service would now be considered if it had previously been rejected by the Admiralty. Colonel HEADLAM said that any new medical evidence which was brought forward would always justify reconsideration of a case. On December 4th Sir L. WORTINGTON FRANKS told Mr. Thurtle that there had been no recent change in the rules laid down to guide medical officers of his department in deciding whether or not cases of tuberculosis which arose during service were attributable to service.

Care of Mentally Disabled Ex-soldiers.—Major TROY told Sir Robert Thomas on November 29th that he could not say how many ex-soldiers were permanently disabled mentally as a result of the war. He hoped that many of the officers and men at present mentally disabled would improve or even recover. In addition to mental hospitals approved under the general lunacy laws, which had been supplemented by two special institutions for certain types of cases, the Ministry provided treatment in institutions for mental trouble short of certifiable insanity or for cases discharged from certificate who needed further institutional care. The provision thus made had been found to be adequate, and no State assistance was given to voluntary institutions providing care and treatment for such cases.

Vermineous Tenements.—Mr. CHAMBERLAIN replying to a question on November 27th said no reports relating specifically to the vermineous condition of tenements had been made by officers of his department. Section 46 of the Public Health Act, 1925, and Section 10 of the London County Council (General Powers) Act 1922 gave ample powers to local sanitary authorities to secure the cleansing of vermineous houses.

Poisoning by Fumes and Workmen's Compensation.—Sir WILLIAM JOYNSON HICKS told Mr. Stephen Mitchell on November 22nd that various forms of poisoning by fumes or gas were already scheduled under the Workmen's Compensation Act. The circumstances of poisoning by gases such as carbon monoxide which took effect rapidly would always be such as to constitute an injury by accident for which compensation could be claimed.

Small-pox.—On November 27th Mr. CHAMBERLAIN informed Mr. Lansbury that the average annual death rate from small-pox during the ten years 1918-27 was for England and Wales 0.0005 for Switzerland 0.0004 and for the Netherlands 0.00006 per 1,000 population. Statistics furnished to Mr. Petrick Lawrence by Mr. Chamberlain on November 28th show that in England and Wales in 1926 the percentage of vaccinations to births was 44.8 in Bedfordshire 12.5 in Gloucestershire 22.2, and in Leicestershire 71. The rate of cases of small-pox notified among civilians per

10 000 of the population in the same year was 2.6 in England and Wales, and nil in Bedfordshire, Gloucestershire and Leicestershire. In 1923 Gloucestershire, with a vaccination percentage of 28.1 had a small pox case rate of 12.8 per 10 000 of the civil population.

Conditions in Distressed Areas.—On December 3rd Mr CHAMBERLAIN, replying to requests by Mr Lansbury and Mr Morgan Jones that the Government should take action to relieve distressed areas said that a fortnight ago he sent a chief inspector to South Wales, accompanied by a competent medical man, to make a thorough investigation on the spot and to go into the homes of the people. The inspector was assisted by people in the district who had taken a special interest in the matter. He (Mr Chamberlain) hoped before long to receive a report which would disclose the situation more accurately than anything he had hitherto been able to get.

Duty on Enamelled Hollow Ware used in Hospitals.—Mr A. M. SAMUEL, on December 4th, replying to Mr A. Alexander, who asked if he was aware that certain enamel hollow ware products mainly used for medical and nursing purposes were being charged with duty, said duty was chargeable on wrought enamelled hollow ware of a description commonly used for domestic purposes. This included articles of the kind commonly used in the home in cases of sickness. Mr ALEXANDER asked if it was the fact that the Treasury promised that a number of the things required for hospitals should be exempted, and that the Surgical and Allied Trades Association now found that promise had not been carried out. Mr SAMUEL said he would look into the matter.

Caseous Lymphadenitis in Imported Mutton.—Sir KINGSLEY WOOD, asked on December 3rd by Mr W. THORNE if he was aware that approximately 10 000 carcasses of imported mutton had been seized and condemned on account of caseous lymphadenitis in an aggravated form that each of the diseased carcasses had individually attached to it a label signed by a veterinary inspector in the country of origin, stating that the meat had been examined at the time of slaughter and found healthy and fit for export and that the character of this disease should show in the majority of these sheep nodules and growths on the offal and viscera of the animal that should have warned the inspector, stated that the Minister of Health was in communication with the Governments of the countries concerned in regard to the matter.

Court of Inquiry on R.A.M.C. Officers.—Earl WINTERTON replying to Sir G. HOLLIER on December 3rd said that in September a court of inquiry was held on the competency of the officers of the Royal Army Medical Corps at Chakrata United Provinces, India. As a result, disciplinary action had been taken. Only telegraphic details were available but the Government of India was sending a full report as soon as possible.

Meals for Accessory Children.—On December 3rd the Duchess of ARTHOLL told Sir R. THOMAS that at present approximately 120 local education authorities were providing meals or other nourishment for accessory children. The authorities in the Welsh coalfields undertaking such provision were Monmouth, Glamorgan, Cardiff, Merthyr Tydfil, Newport, Swansea, Aberdare, Aberllynny, Barry, Pontypool, and Rhondda. Arrangements had been made for securing close co-operation between the education and the Poor Law authorities.

Infant Mortality in Depressed Areas.—Mr CHAMBERLAIN told Mr RHYL Davies on November 22nd that the infant mortality rates in the depressed areas during the present year appeared to show some improvement over those of the preceding year. No useful purpose would be served by publishing figures till statistics were available for the whole year.

Notes in Brief

The London animal quarantine station was approximately full from July 24th to October 26th. South Africa, Southern and Northern Rhodesia, the Irish Free State and Palestine have signified their readiness to accept pedigree stock through the station.

Mr Chamberlain is of opinion that though overcrowding and deficient sanitary accommodation contribute to the spread of certain infectious diseases there appears to be no need for further inquiry on this subject.

The Ministry of Health has not decided on any design of refuse cart as being most generally suitable.

The average annual increase of population in England and Wales between the 1921 census and mid 1927 is estimated at 234 000.

The Minister of Health is advised that local authorities possess powers sufficient to secure any necessary disinfection of premises in which tuberculosis has occurred.

There are no general Government regulations on the storage of benzol.

Lord Eustace Percy believes that education authorities generally appreciate the importance of the prompt provision of spectacles to children with defective eyesight. He will not advise local authorities to give permission to headmasters immediately to purchase glasses for these children.

Lord Eustace Percy is not aware that the provision of a disinfectant mouth wash for use by school children would prevent the spread of infection. He says that in any case it is for the local authorities acting on the advice of their medical officers to consider methods of combating the spread of infectious disease.

Obituary

JAMES WILKIE SMITH, M.D., C.M.,

Late President, North of England Branch, British Medical Association

We regret to record the death of Dr James Wilkie Smith at Ryton-on-Tyne, on November 21st, at the age of 76.

James Wilkie Smith received his medical education at Edinburgh, where he graduated M.B., C.M. in 1873, and proceeded M.D. in 1879. He was pre-eminently a general practitioner, carrying on a very extensive practice until the time of his death. On this sure foundation he built up an active interest in public health, being a Fellow of the Society of Medical Officers of Health, and at one time president of the Northern Branch. He received the degree of D. Hy. Duncelm *honoris causa* in 1921. The deep and sympathetic interest he took in his colleagues and their work rendered him a highly-welcome member of medical societies.

Dr Smith rendered devoted service to the British Medical Association and held many posts. He was a member of the North of England Branch Council from 1906 to 1919, 1924-25, and 1928. He was vice-chairman of the Newcastle-on-Tyne Division in 1907, chairman in 1908, representative from 1909 to 1923, and a member of the Executive Committee in 1926 and 1927. He was president of the North of England Branch in 1918, a member of the Arrangements Committee 1920-21, and a member of the Contract Practice Subcommittee from 1920 to 1922. Dr James Smith was also vice-president of the Section of Medicine at the Annual Meeting at Newcastle-on-Tyne in 1921.

We are indebted to Professor G. GREY TURNER for the following tribute.

By the death of Dr James Wilkie Smith the profession in the North has lost, if not its oldest, certainly one of its best known and most highly respected members. He was the elder of the well-known brothers Smith of Ryton and Whickham respectively, and for well nigh fifty years no medical function of importance in this district was complete without him. It may truthfully be said that he only very rarely missed a medical meeting, and this applies to the social as well as to the academic variety. He personally contributed to every sphere of activity of the British Medical Association and the local medical societies, and he had held office in all of them. The most remarkable feature about the late doctor was his sustained and undiminished interest in everything that concerned the welfare of his profession. Up till the very end he was active in every way, not only in practice, but in other respects, and within the last year or two he had attended post-graduate classes held in Newcastle in connexion with the University of Durham, and had also made a pilgrimage to St Andrews, where he sat at the feet of one of his competers, the late Sir James Mackenzie. Early in life he discovered that the master word in medicine is Work, and to the very end he cheerfully bowed to its dictates, and he died as he lived, in the exercise of his beloved profession. For thirty-three years the writer enjoyed the acquaintance—which early ripened into close friendship—of James Smith, and during all that time he has been recognized as one of the most stimulating personalities, whose main endeavour was to bring out the best in everyone around him.

In the early days of abdominal surgery Smith was closely associated with his old friend and one-time neighbour Rutherford Morrison, and he was a constant visitor to the operating theatre of the old Royal Infirmary. No one could be keener to recognize the great changes which were then coming over practice, and no one readier to grasp the advantages of early operation, especially in the acute abdomen. Discouragements frequently strewed the path in those days, but, with an unswerving faith and absolute loyalty, James Smith persisted in persuading successions of patients to come into hospital and to accept the possible benefits of surgical intervention rather than the risks of the waiting policy, of which he had seen so much in his still earlier days. Probably on looking back James Smith will be longest remembered by that large and loyal band of men

who started their professional life as one of his many assistants, and who got from him, not only a sound and thorough practical training in medicine, but also in those high ideals which were part of his innermost nature, and which by example he radiated to all who came in contact with him. For many years he commanded a large practice in an extensive colliery and country district, which could only be worked with the help of several branches, but he was always, and in every respect, the head of the "firm," and he made it a rule to visit very part of his district several times a week. Though personally never keen on the technical side of surgery, he always encouraged his juniors to do what they could in the smaller houses of the industrial classes, and his Sunday morning clinics were in many respects like the operative session of any general hospital.

His outlook was extremely broad and liberal, and in the ordinary affairs of life he came to be looked upon as a sort of standby to whom younger men could refer in their troubles. He was exceedingly fond of literature, and had a wide knowledge of all that is best in the English language, even in the days of the dog-cart it was usual to see him poring over one of his favourite books when out on his rounds. Poetry was his favourite, and he was himself responsible for one or two productions well worthy of his time and station, none that he is no more one realizes that his poem *The Iud Doctor* is a faithful picture of himself. He loved the country and flowers, and up to his last days he was seldom seen without his inevitable buttonhole.

Though never willing to avoid trouble merely for the sake of the easier path, he was nevertheless of a conciliatory nature, and whoever sought his advice, on whatever subject, could always feel assured of a sympathetic ear, and would always find the doctor the same wise but unobtrusive counsellor and friend. Though injured to family affliction he was not in any way soured, and was ever happy in his family circle, among his very many friends, both professional and otherwise, he had earned a deep affection. Just after the war he was the means of giving to Newcastle its Medical Institute in memory of one of his sons, cut off in early life. His idea was to have a centre of medical activity where all that was best could be brought together, and where medical men of all stations and of all ages could congregate in good fellowship for their mutual well being.

Years ago James Smith told me that he had been re-reading *Don Quixote*, and that mature consideration had shown him that it was full of the profoundest wisdom. During the latter years of his life Smith himself had attained the master work of Wisdom, for he had learnt to grow old without showing it. As Stevenson has it, though slightly paraphrased, "True as a physician, in the widest sense, he was one of the flowers of our civilization, and shared as little as any in the defects of his period and most notably exhibited the virtues of his race." It was indeed a privilege to have known him.

Dr N. H. RAWSON writes

May I, as one of his late assistants, pay a final tribute to that most lovable of men, James Wilkie Smith of Ryton-on-Tyne? Our memories linger fondly on those days when we wandered round the practice with our chief, chatting with the miners and their wives—Smith's friends for many years past—and between the visits quoting Wordsworth or other poets, but chiefly Wordsworth, when not Bobbie Burns. Then those quiet evening chats on medicine—difficult points in our own case, oddities, the masters, past and present—to many of us the first glimpse into the history and philosophy of medicine. But his chief message was the importance of the fellowship of men, of the meeting of colleagues. His constant smile, his ever-ready sympathy, and his keen interest endeared him to all. He of all men knew the value of intercourse, and he joyed to take us to the medical gatherings, whether social functions or scientific meetings. In the hope of providing a place where men might forget their for discourse, as in the Athenian market-place, he gave the profession the institute, which bears the name of a beloved son.

For some years he had been in failing health, but whenever possible he had been as eager as ever, whether as president of the Newcastle-upon-Tyne and Northern

Counties Medical Society, or attending meetings of the British Medical Association, locally and elsewhere, round the beds as a student in the post-graduate class, or dining out. Quite recently it has been my privilege to meet him in his old gay spirit at two such functions—the one at the Bohemian Pen and Palotto Club to welcome an intrepid pioneer in adventures of the air, the other at a monthly dinner of local country practitioners, where he was our honoured guest. Such was his keenness that on the very day he laid his body to rest he was to have joined our table as a fellow member. In the North things live. The Association is at its strongest, and we have given of the noblest to the cause of the profession. Clinical societies and post-graduate courses flourish, while dinners, dances, golf meetings, and other social gatherings meet with a ready response. It is to men such as Smith that the present generation owes this happy heritage. While his body rests in well-earned peace, may his spirit live in the hearts of his successors.

THE MEDICAL SECRETARY writes

I deem it a privilege to be allowed to add a few words of tribute to my old friend. When I was in practice in the North, not far away from Ryton, I learned to regard the Smith brothers first with great respect as men who knew their job and did it, and later—particularly with regard to James Smith—with affection. I have rarely known any man whose judgement I would sooner trust, his knowledge of his profession was wide and sound, and his relations with his patients, with his assistants, and with his medical neighbours were ideal. During the course of my official career, when I have had cause to defend the general practitioner, the ideal I have had in mind has been a blend of John Brown of *Hub and His Friends*, Ian MacLaren's doctor of the old school (William MacLure), James Mackenzie, and James Smith, with the last named pre-empting, because I knew him well in the flesh. James Smith has left behind him a fine legacy in the shape of the Medical Institute in Newcastle, but a still finer in the deep impression he left on the mind of every man with whom he came into close contact. He was a good man in every sense of the term.

WILLIAM SMITH KERR, M.B., C.M., F.R.C.S. ED.,
Honorary Surgeon, Ear, Nose and Throat Department,
Sheffield Royal Infirmary.

We regret to announce the death of Mr W. S. Kerr, F.R.C.S. Ed., which occurred at his home in Sheffield on November 26th.

William Smith Kerr received his medical education at the University of Edinburgh, where he was Thomson Bursar from 1886 to 1890, in which year he graduated M.B., C.M. He was admitted to the Fellowship of the Royal College of Surgeons of Edinburgh in 1903. After holding a resident post at the Dumfries and Galloway Royal Infirmary he became senior house-surgeon in the Royal Infirmary in Sheffield, so commencing an association with the institution and the city in which he ultimately attained a leading place as an aural surgeon. At the time of his death he was honorary surgeon to the ear, nose, and throat department, and consulting aural surgeon to the Sheffield Union Hospital and to the Yorkshire Institute for the Deaf at Doncaster. He was also lecturer on diseases of the ear, nose, and throat in the University of Sheffield.

Mr Kerr was the author of a number of contributions to medical literature, and took a prominent part in professional affairs. In the Sheffield Medico-Chirurgical Society he had held the offices of president, secretary, and librarian, he was a member of the Laryngological Section of the Royal Society of Medicine, and at the annual meeting of the British Medical Association at Exeter in 1908 he acted as secretary of the Section of Laryngology, Otology, and Rhinology. In the Sheffield Division of the Association he was vice-chairman in 1912 and chairman in the following year, and for the past seven years had been a member of the executive committee. He had served in the Territorial Army with the R.A.M.C., and retired a few years ago with the rank of lieutenant-colonel. Mr Kerr is survived by his wife.

GEORGE WILLIAM HILL, M D, F R F P S,
Sargeon for Diseases of the Ear, Nose, and Throat to
St Mary's Hospital

THE news of the death of Dr William Hill at the age of 70, on November 24th, has come as a shock to innumerable members of the medical profession and as a cause of profound grief to the large body who numbered themselves among his friends.

Hill received his medical education at St George's and St Mary's Hospitals, he gained the Senior Entrance Science Scholarship at St Mary's and won many prizes, among which was a scholarship in pathology. It was, indeed, as pathologist that he received his first appointment at the Central London Throat and Ear Hospital, which probably directed him towards the special line of practice of which he was so distinguished an exponent. He graduated M B Lond with honours in 1885, and proceeded M D four years later, in 1923 he obtained the diploma F R F P S Glas. After two years of general practice in Cornwall his native county, he returned to London, and became at St Mary's a teacher of anatomy, then auricular surgeon, and finally surgeon to the combined ear, nose, and throat department.

DR WILLIAM HILL

Endoscopic methods of examining the bronchi and oesophagus attracted Hill when he was at his most receptive stage, and he became an adept in them, extending their scope to the stomach, for which he designed an improved form of gastroscope. He contributed to the literature a valuable monograph, and collaborated with the late Dr Herschell

So also he did with Dr Finzi, when Hill's tubes and other oesophagoscopic apparatus were invented for the purpose of introducing radium with accuracy into malignant strictures of the oesophagus. His official retirement was due just when radium treatment was reaching its present maturity, but the staff and authorities of the Metropolitan Ear and Nose Hospital secured him as endoscopic surgeon, so that up to the last his activity in this "specialty in the specialty" was maintained.

In whatever society he took part he came well to the front. He was vice-president of the Section of Otolaryngology at the Annual Meeting of the British Medical Association in 1890 when it met in Birmingham, and president of the Section of Oto-Rhino-Laryngology at the Annual Meeting at Newcastle-upon-Tyne in 1921. He was a member of the executive committee of the Marlebone Division for 1925-28, deputy representative in the Representative Body for the Marlebone Division in 1927, and a member of the Metropolitan Counties Branch Council in 1927. He was president of the Laryngological Section of the Royal Society of Medicine and of the Harveian Society, and also vice-president of the original Laryngological Society of London. He was a very popular and prominent member of the Masonic body, and held the coveted rank of Past Grand Deacon in the Grand Lodge of England.

Hill's personality was singularly attractive, and not infrequently in mixed gatherings the question was put who "the good looking man with the red beard" was. His humour was exuberant and to some degree boisterous, but the manifest genuineness of his enjoyment of his own sallies

and his delight in amusing his audience made it acceptable even to the most fastidious. He delighted to "set the table in a roar." It might have been felt that one never knew what he would say next, but one knew well what he would never say—namely, that he had inmostentatiously helped many a lame dog with material assistance or sound advice in time of need. His peculiarities were patent, and any faults were all on the surface, the heart was of gold. His scientific information was exceptional, and those who identified him chiefly as the privileged jester scarcely realized what an amount of wisdom and knowledge was to be found under his jolly exterior.

It was the writer's great good fortune to have come into intimate contact with William Hill at a very early period in their careers. Hill was appointed pathologist to the Central London Throat and Ear Hospital when the writer was junior assistant surgeon, and Hill became his clinical assistant at the evening clinic. The co-operation was a happy one, and if it was the starting point in Hill's brilliant career as an otologist, it was a most inspiring and inspiring epoch in the life of the old friend who now mourns his loss. J D G

THE LATE SIR HECTOR CAMERON

Dr J GRANT MILLAR (Leicester) writes

As a former student and house surgeon of the late Sir Hector C. Cameron may I be allowed to add a few words to the many tributes I feel sure you will receive about him? Sir Hector and my father were very old friends, so that I had the privilege of knowing him from a child. As a surgeon at the Western Infirmary what I think impressed me most as a student was his kindness and consideration to all hospital patients, and, perhaps, especially, to all female patients. He was most particular to avoid exposing them unnecessarily, and never allowed students to examine them unduly if there was the smallest chance of the patients suffering therefrom, or if they were unusually sensitive about the matter. In those days—I speak of some thirty years ago—Sir Hector used to receive, among others, many cases of cancer of the breast, sent to him from all over the West of Scotland. Some patients, alas! only reached him when the disease was too far advanced to render operating any use, and I well remember the gentleness with which he would explain it was too late for any operation to be effective. At that time cancer was even a more dreaded disease than now, and many sufferers delayed seeking relief until the breast was a great fungating mass or a dense scirrhous growth with hopelessly widespread glandular enlargement. As a teacher Sir Hector Cameron was direct and graphic. An illustration of this I remember when he was speaking about the dangers of fully emptying a bladder which had been overdistended for some time and in which difficulty had been experienced in passing a catheter. He vividly portrayed the delight of both patient and surgeon when the urine commenced to flow, but warned the students against too complete an evacuation, lest it should be followed by a possibly severe secondary hæmorrhage. It was the graphic manner in which it was done that left an indelible impression. Of his kindness to poorer patients I could tell many stories. Let one suffice. There was a student—not in medicine but in arts—who was suffering from psoas abscess and hip joint disease in an advanced form. His case was brought to Sir Hector's notice, and for two years he attended that young man at the patient's own home, driving out to see him twice or three times a week, and supplying all dressings, appliances, and so on, at his own expense.

Personally Sir Hector Cameron was very genial, a born storyteller, and with a keen sense of humour. He was in great request as a guest for dinner parties. He was a very fine golfer—as befitted a St Andrews man—and was also a good shot. For these recreations he had, of course, little time, but during his active life he made a point of taking a long, summer vacation of some five or six weeks, and no doubt that helped him to keep well and to live to the ripe old age at which he has just passed away.

EDWARD KNIGHT, M R C S, L S A

We are indebted to Sir James Dundas-Grant for the following notes concerning the late Edward Knight.

Edward Knight was for many years teacher of anatomy at, and later sole director of, "Cooke's School of Anatomy." He was exceptionally gifted in carrying on instruction by means of quick question and answer on the

dissected part. Being possessed of a cheerful and rather peculiar disposition in a handsome and somewhat commanding person, he was well adapted to keep the attention of those who were just "learning to learn," while many candidates for higher examinations found it beneficial to be put rapidly through their paces by this energetic and sprightly coach. Knight had mixed eye anatomy at his fingers' ends, and knew Cooke's wonderful tablets through and through. These anatomical "tablets" were by no means "tabloids," but pretty solid doses of anatomy in which the regional and systematic methods were cleverly blended. The extraordinarily systematized and intensive courses allowed of a rapid survey of the unked-eye anatomy of the whole body in the shortest possible space of time. The work for the teacher was extremely hard, and there is every probability that the strain, even on this vigorous man, led to the progressive disease of which, after a considerable number of years of poor health, he died at the age of 69. Many of Knight's pupils have, no doubt, pre-deceased him, but there must be still a number remaining who will remember with gratitude his "clinking" and his "cranking," and will take pleasure in reviving their memory of him.

The Services.

HONORARY PHYSICIANS AND SURGEONS TO THE KING

The following revised regulations governing the appointment of Honorary Physicians and Surgeons to the King have been issued:

Medical officers appointed as such are in future to relinquish their honorary appointments on retirement from the Service. Officers on the retired list at present holding the appointments are to continue to hold them. The officer holding the position of Medical Director General of the Navy is to receive *ex officio*, an appointment as Honorary Physician or Honorary Surgeon to the King.

The total number of Honorary Physicians or Honorary Surgeons to the King is to remain at eight, excluding extra or super-numerary appointments, but the number of these appointments is to be varied at discretion within the total instead of four of each being allowed as hitherto. Officers in order to be eligible for appointments are to be of the rank of surgeon captain or above.

DEATHS IN THE SERVICES

LIEUT. COLONEL JOSEPH PARKER Bombay Medical Service (retired), died on September 12th, aged 75. He was born on April 10th, 1853, the son of Mr. Joseph Parker of Limerick, was educated in Ireland and graduated as M.D. and M.Ch. in the Queen's University, Ireland, in 1875. Entering the I.M.S. as surgeon on September 30th, 1875, he became surgeon lieutenant colonel after twenty years' service, and retired on May 16th, 1901. He served in the Borneo campaign of 1886-87, receiving the frontier medal with two clasps, and in the China war of 1900, when he was present at the relief of Peking and got the medal.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Raymond Horton Smith prize for the best M.D. thesis during the academic year 1927-28 has been awarded to Hugh Galtsborough M.A., M.B., B.Ch. (Downing). *Proxime accessit* Erle Gordon Holmes M.A., M.B., B.Ch. (Christ's).

UNIVERSITY OF LONDON

THE Paul Philipps Reittlinger prize offered this year for the best essay embodying the result of research work has been awarded to Geoffrey William Rake L.R.C.P., M.R.C.S., a student of Guy's Hospital Medical School, for his essay on achalasia of the cardia. The prize of the value of £30 was founded with funds given to the University by Mr. Albert Reittlinger in memory of his son, a student of Middlesex Hospital Medical School who died on December 3rd, 1911.

Kathleen A. H. Sykes M.D. has been approved at the examination for the diploma in psychological medicine with special knowledge of psychiatry.

UNIVERSITY OF LIVERPOOL

The title of 'Professor Emeritus' has been conferred on Dr. J. W. W. Stephens F.R.S. until lately Alfred Jones Professor of Tropical Medicine in the University.

Medical News.

THE British Medical Association will be represented by Sir Robert Philip at the International Congress of Tropical Medicine and Hygiene, which opens at Cairo on December 15th. Other delegates include Sir George Newman, representing the Ministry of Health, Sir Herbert Waring, the University of London and St. Bartholomew's Hospital Medical College, Sir St. Clair Thomson, the Royal Society of Medicine, and Sir Berkeley Moynihan, who, as President of the Royal College of Surgeons of England, will present the diploma of honorary Fellowship of the College to Dr. Aly Bey Ibrahim in the course of the congress.

A DISCUSSION on alcohol and drug addiction in relation to women and children will be opened by Dr. Catherine Chisholm at the meeting of the Society for the Study of Inebriety at 11, Chandos Street, W.1, on Tuesday, January 8th, 1929, at 4 p.m.

AT a meeting of the Pharmaceutical Society of Great Britain, to be held in the lecture theatre of the society's house at 17, Bloomsbury Square, W.C., at 8 p.m., on Tuesday, December 11th, an address will be given by Miss Katherine H. Coward, D.Sc., biochemist in charge of the vitamin department of the society's pharmacological laboratories, on "Recent research on the vitamins." The lecture will be illustrated by lantern slides. Medical friends of members and student associates will be welcomed.

THE fourth congress of French Dermatologists and Syphiligraphists will be held in Paris, at the St. Louis Hospital, from July 25th to 27th, 1929. Papers will be read on the polymorphic erythemas, prurigo, and the malarial treatment of the nervous complications of syphilis. Further information may be obtained from the general secretary, Dr. Clément Simon, 104, Avenue Malakoff, Paris XVI.

THE Fellowship of Medicine and Post-Graduate Medical Association announces that a lecture will be given on Monday, December 10th, at 5 p.m., by Dr. Bernard E. Schlesinger on "Spasmodic respiratory affections in childhood." In the lecture room of the Medical Society of London, there is no fee for attendance. There will be no further special courses or special lectures and demonstrations until the middle of January. The next series of lectures is entitled "Pitfalls in medicine and surgery," and, as before, the lectures will be given on Mondays, at 5 p.m., at the Medical Society of London, and will be free to all members of the medical profession. From the middle of January until Easter there will be, each week, clinical demonstrations in medicine and in surgery at various hospitals, and also a series on Wednesday, at 4 p.m., at the Wellcome Museum of Medical Science, all are free to members of the medical profession. The first special courses in 1929 commence on January 14th—one in cardiology at the National Heart Hospital, and one in diseases of children at the Queen's Hospital for Children. The general course of work, consisting of attendance at the clinical practice of from forty to fifty London general and special hospitals, continues throughout the year. Tickets may be taken out on any day of any week from now onwards. Copies of all syllabuses and of the general course programme are obtainable from the secretary of the Fellowship, 1, Wimpole Street, W.1.

THE sum of £129 was raised at a sale held on behalf of the Glasgow Branch of the Royal Medical Benevolent Fund Guild on November 20th, at 21, Woodside Place (by kind permission of Mrs. Ingalls Pollock). Four performances, commencing on November 21st, were given by a well-known Glasgow amateur dramatic company, the Albany Players, for the same object, and, while it is not yet possible to state what amount has been secured, the attendance was very good and the financial result should be satisfactory. The play presented was a light comedy, entitled "Healing Waters," by Dr. John Fergus.

DR. H. B. NEWHAM, C.M.G., warden of studies, has been appointed also curator to the museum of the London School of Hygiene and Tropical Medicine. Dr. J. T. C. Haslam, has been appointed Director of Library Services.

READERS who knew Amiens and district during the war will be interested to learn of the approaching publication of the town's official history (1914 to 1918), illustrated with 450 photographs and 30 coloured prints. Since the edition will be limited those desiring further information should communicate without delay with M. le Maire, Hôtel de Ville, Amiens, who will gladly send them a descriptive brochure.

A GIFT of £3,000 has been made to Doncaster Infirmary by Mr. William Nuttall, a confectionery manufacturer, for the purchase of radium for cancer treatment. Mr. Nuttall has also given £3,000 to the Leeds Infirmary Fund and £1,000 to the Yorkshire Cancer Research Fund.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are MUSEUM 9861, 9862, 9863, and 9864 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are EDITOR of the *British Medical Journal*, Anthology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.) Articulate Westcent, London.

MEDICAL SECRETARY *Mediscera Westcent* London.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Barilrus*, Dublin) telephone 62550 (Dublin) and of the Scottish Office 7 Drumshugh Gardens, Edinburgh (telegrams *Associate*, Edinburgh) telephone 24361 (Edinburgh).

LETTERS, NOTES, ETC.

COMBINED HELIO- AND RADIO-THERAPY IN HODGKIN'S DISEASE

DR A. GORDON WATSON (Bath) writes: With reference to radio-therapy in Hodgkin's disease (*Epitome*, November 24th para 411) I have combined x-ray therapy with ultra-violet light therapy in the treatment of Hodgkin's disease on the presumption that ultra-violet rays cured some x-ray burns and the results seem encouraging. I append notes on a case that seemed hopeless. A married woman aged 52, consulted Dr. Kenneth Watson on February 13th 1926, after a complete examination he diagnosed Hodgkin's disease or lymphosarcoma and gave a very grave prognosis with expectancy of life for a few months only. On the next day Dr. Forbes Mackay started x-ray therapy and gave three full doses interrupting the x-ray treatment on February 17th and continuing between the x-ray doses ultra-violet light irradiation of the whole body, and giving a first degree erythema dose to a quarter of the body surface every other day. This was continued until the patient was again exposed to x-rays on March 4th, 5th, 6th, and 8th followed again by ultra-violet irradiation. The whole picture had changed by this time, the weight had increased from 8 st 3 lb to 8 st 9 lb and the glands had almost disappeared. On September 22nd, 1926 the weight was 10 st 8 lb and the patient had long been attending to her duties as usual. X-rays were given again on May 20th and July 28th 1927. In July 1928 she had an attack of fever and general malaise while at the seaside, and on her return in August I found the glands enlarged. She again had x-ray and ultra-violet light treatment and has made a good recovery, she is at present a normal person for her age. Her weight is now 11 st, there is very little anaemia, no debility, and only a feeling of "brawiness" where the glands were largest.

WEIGHT AT BIRTH

DR W. L. HUBBARD (St. Leonards-on-Sea) in a letter thanking Dr. D'Ewart for reprinting (November 24th p. 962) to his inquiry published in the *Journal* of November 10th (p. 878) as to the chances of survival of a child weighing 1 lb at birth writes: The child is now six weeks old in good health and weighs 32½ oz. It is being fed on breast milk from a bottle with one feed daily directly from the breast. The weight at birth was 15 oz.

D. HERBERT SHACKLETON (Bradford) writes: I am sending a card of to-day's weight (24½ lb) of a child born February 27th, 1927, weighing 17 oz. The child was reared on a proprietary food. She is intelligent and bright, and ran about the surgery for us to night.

ANTENATAL CARE IN GENERAL PRACTICE

A COUNTRY DOCTOR'S WIFE writes: I was interested in the discussion on antenatal care in general practice reported in the *Journal* on November 17th (p. 899) and thought the following notes might be of general interest. My husband practises in a very big rural area, the nearest hospital being seventeen miles away. During the course of his practice he has been up against many abnormal maternity cases very worrying to him as well as and from the mothers' point of view. I came to the conclusion that much distress could be avoided and so at my house we have started an antenatal class. Once a month Dr. K., the welfare doctor and tuberculosis officer attends and brings two council nurses, the district nurse is here if available and my husband also. The mothers sit and talk in the dining room

and drink tea and one by one Dr. K. sees them in our surgery, which is convenient and warm. All wives are tested here the same day, and if anything abnormal is found we can be prepared for it and watch the patient approaching term. My husband has so often in the past been called out to a patient he had never seen previously, and by this arrangement a lot of trouble has been saved. Would it not be a good plan if all rural doctors wives did this since it is no trouble, but rather a joy to the mothers to come out to tea, and it is also a great relief to the doctor, who knows what he has to tackle when the time comes?

PIONEERS IN TYPHUS FEVER RESEARCH

DR JAMES MCQUEEN (Halesowen) writes: All your readers will join with you in the pleasure felt in the recent award of the Nobel Prize for Medicine to Dr. Charles Nicolle in recognition of his work on typhus fever, but the pioneer work from the side of epidemiology by Professor Matthew Hay embodied in his report on an outbreak of typhus fever in Aberdeen where the transmission of the disease through body vermin was clearly indicated, deserves more recognition than it has ever received. I am writing away from a library where I could check details, but I believe all the preventive measures against infection and the spread of the disease were clearly outlined by Professor Hay on the basis of a transmission of the disease by body vermin.

ANATOMICAL CONSIDERATIONS IN INTRAMUSCULAR INJECTIONS

MESSES K. G. ZWICK and O. V. BATSON of the department of anatomy in the University of Cincinnati have made an experimental study of the sequelae of intramuscular injections in fresh and preserved cadavers. In the November 9th issue of *Science* they report that whatever way the injecting needle may point the introduced solution travels in the direction of the muscle fibres. In the case of the gluteus maximus the injected fluid made its way among the muscle fibres to the dependent portion laterally in the usual prone position of the cadaver and in the general direction of the trochanter major. As a practical conclusion the authors recommend that intramuscular injections should be made with the shaft of the needle parallel with the general direction of the muscle fibres, and that the point should be directed towards the dependent portion. In the case of such muscles as the deltoid, triceps and gluteus maximus which are usually employed for injections, this recommendation secures anatomically the avoidance of the large vessels and nerves.

THE THERAPEUTIC INJECTION OF INORGANIC SALTS

DR B. A. LEROTT, president of the Russian Medical Association of Great Britain calls our attention to a monograph by Professor S. F. Maykoff on the subject of the action of hypertonic solution of inorganic salts in various conditions. Professor Maykoff, who for many years has been using a mixture devised by Dr. Trnecsek, has in conjunction with Professor Schilloff modified this salt so that the formula reads:

Distilled water	100.0
Sodium chloride	4.92
Sodium phosphate	0.45
Sodium bicarbonate	0.42
Sodium sulphate	0.44
Potassium chloride	0.35

He states that this solution has a neutral reaction, and can be sterilized. It is stored in ampoules of 1, 2 and 25 c.c. The solution is said to act by absorbing calcium deposited in the blood vessels, and may be given by any form of injections or by the mouth or in enemas. Internally one tablespoonful is administered twice daily, after meals, for a period of four months. In enemas 100 c.c., with one or two tablespoonfuls of hypotonic solution, is used every day for ten days, and then every other day until about sixty enemas have been given. After six months time the treatment is repeated the quantity of the enema being half that of the first course. Intramuscularly the dosage is 1/2 to 5 c.c. The best results are said to be obtained by intramuscular injections and the next best from enemas. The treatment has been recommended for such conditions as sclerosis of the brain vessels, neurasthenia, arteriosclerosis, migraine, presbyopia, otosclerosis and other conditions in which calcium deposits are concerned.

A DISCLAIMER

SIR ROBERT ARMSTRONG-JONES M.D. writes: In a Sunday paper recently there purports to be an interview granted by me accompanied with a signed article upon "spiritual healing." May I say that no interview was given nor any signed or unsigned article contributed to this paper. The only intimation I received was the unauthorized appearance of my name and I have communicated with the Medical Defence Union upon the matter.

NATIONAL SUN RAY AND HEALTH CENTRES LTD

DR. PERRY HALL (London, W.) writes: I beg to inform you and to request that you will be good enough to make it known in your columns that I have entirely severed my connexion with the above named company.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 44, 45, 46, 47, 50 and 51 of our advertisement columns and advertisements as to partnerships, assistantships and locum tenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement column appears in the *Supplement* at page 255.

Remarks

OF

ACUTE HAEMORRHAGIC NEPHRITIS.*

BY

H. LETHBRIDGE TIDY, M.D., F.R.C.P.,
Assistant Physician, St. Thomas's Hospital

In acute haemorrhagic nephritis the outstanding and frequently the sole immediate characteristic is the occurrence of gross renal haemorrhage—often this is directly related to infections in or around the throat. Otherwise there is no marked constant feature.

This condition is somewhat mysterious, and in textbooks of medicine it is practically unmentioned. There is, however, a considerable literature on the subject, mainly, until recently, by Continental and American authors. Hale-White, writing in 1911 under the title "essential renal haematuria," gave references to 120 articles. Among children it has been studied in recent years especially by Paterson, Wyke, Moncrieff, and L. G. Parsons. Many cases in adults pass into oblivion with a diagnosis of "essential haematuria."

The cause of this neglect is partly the fact that the immediate mortality is negligible, and even the remote effects are rarely serious or obvious. Further, the condition presents little, and usually none, of the ordinary features of acute nephritis apart from haematuria. But it is often the cause of much anxiety and of extensive biochemical and surgical investigations, occasionally, though rarely, it runs a serious course. The frequency with which such a course occurs is uncertain, and the progress is always very slow, but it is remarkable that the literature contains practically no examples where such cases have been followed deliberately to their end, the symptoms described, and the pathological changes recorded. This knowledge is still wanting.

The term "acute haemorrhagic nephritis" may be used provisionally to distinguish this condition from what may be referred to as "acute parenchymatous nephritis." As to its frequency, it is certainly not rare, all records from hospital wards show that it is commoner than acute parenchymatous nephritis. Even this underestimates its occurrence, for in an out-patient department one sees patients who attend once or twice and then disappear permanently, no doubt due to the absence of any further symptoms.

Etiology

Age Incidence.—It is impossible to make any definite statements as to age incidence, since the condition has nearly always been studied separately in children and adults. It is certainly most common in children and young adults, but may occur even after the age of 50. The frequency mainly follows that of the predominant predisposing factor. The sexes are equally affected.

Predisposing Factors.—In children there is direct relationship in a high percentage of cases to definite infections in and around the throat, this is obvious in about 75 per cent of cases, and differs from the relationship of acute parenchymatous nephritis to such infections, first in the far higher percentage, and secondly in the more definite nature of the infection, such as frank tonsillitis or marked cervical adenitis. Many cases may occur in epidemics, as in some outbreaks of glandular fever.

There are, however, cases in which no such predisposing factor can be traced, these are less numerous in children than in young adults and adults, and the latter are consequently more often investigated for possible surgical causes. It is noteworthy that scarlet fever is not a special cause of acute haemorrhagic nephritis, the association nowadays is evidently rare. This is referred to by Paterson and Wyke and by Horder. Syphilitic nephritis is not included in the group. An hereditary and familial form has been reported in one or two families and studied especially by Hurst, but it is very rare.

Symptomatology

The characteristic feature is the sudden passage of a large amount of blood in the urine; the colour is often bright red, and on standing there is no gross microscopic sediment. The amount of albumin corresponds approximately to the quantity of blood. In the deposit, after centrifugalizing, red cells are predominant, there is no excess of leucocytes. In the early stages cellular and granular casts may be found, but they are scanty in number and their presence is transient. The deposit is thus very different from that of acute parenchymatous nephritis. The occurrence of oliguria was emphasized by early writers. It is, however, unusual, but, as J. C. Parsons noticed, it may occur and terminate in a sudden polyuria practically free from blood.

Bacteriological examinations are nearly always negative. Occasionally striking cases occur in which the same organism is isolated from the urine and from pus from an abscess in the neck. But cultures are usually sterile even when a definite infection can be recognized in or around the throat.

The haematuria not infrequently occurs one to two weeks after the subsidence of a preliminary tonsillitis or adenitis, in such circumstances there is rarely any general symptom other than some lassitude. This also applies to cases in which there is no obvious predisposing factor, as in many adults. In some instances the haematuria develops before the preliminary infection has subsided. In such cases, as Paterson and Wyke observed, there may be development of, or exacerbation of, headache, pyrexia, and abdominal discomfort.

The classical symptoms of acute parenchymatous nephritis are not found. Oedema is usually entirely absent, when it can be observed it is generally only a slight puffiness of the eyelids, or more often a pallor of the face with puffiness of the forehead. The heart, the blood pressure, the retinae, and biochemical tests show no variation from normal. Cystoscopic examinations show that the bleeding may come from either one or both kidneys.

Cases undoubtedly occur in which, with the onset of renal haemorrhage, as described previously, there is some more generalized oedema with or without a rise in blood pressure. In such instances the diagnosis may be doubtful, but this should not obscure the fact that in the great majority of cases there is a distinct difference in the symptomatology and progress of acute haemorrhagic and acute parenchymatous nephritis.

Course and Prognosis

The haematuria, so far as it can be recognized by the naked eye, disappears rapidly in the great majority of cases—frequently in three or four days. In a few instances it may persist for three or four weeks, and at times, especially in children, cease after tonsillectomy. In a very occasional case it may continue for months.

It is in general the aim of a hospital or those in charge of a patient to keep the case under treatment and observation until all albumin is absent and no red cells are found after centrifugalizing. In a certain number of cases this is impossible owing to the clinical recovery of the patient and the long persistence of a trace of albumin and a few red cells.

An important question is the prognosis in such cases and their ultimate course.

In a series of children the urine at the time of discharge, approximately in 75 per cent of cases, will contain no albumin or red cells, and in these there need be no anxiety as to the future. Of the remaining 25 per cent the clinical condition will be good, and the amount of albumin and red cells will not exceed a trace in 20 per cent, leaving an occasional unsatisfactory case. Such a case will be marked by general ill health and the persistence of definite albumin in the blood, which may be accompanied by a low result of the urea concentration test, occasionally with a slight rise in blood urea.

If such a series be re-examined after the lapse of several years, it may be stated that approximately 50 per cent will be clinically in normal health, and the urine contain no albumin or red cells, while in 50 per cent some albumin and red cells will be present. A death attributable to the disease is rare within three to five years.

* Made in opening a discussion in the Section of Medicine of the Annual Meeting of the British Medical Association Cardiff 1923.

The question arises as to the future progress of the 50 per cent of the patients who are passing albumin and red cells. Several observers have given the results of the clinical condition in series of cases without recorded reference to the mine. Some of these have been after long intervals. It is clear from these that any appreciable ill health is only present in a very occasional case, certainly not approaching 50 or even 25 per cent. It can consequently be assumed that the mere presence of some albumin and red cells in the urine at the time of discharge, or after an interval of several years, has not necessarily a serious import. About half these patients will be in perfect health without any abnormal physical signs, no future progress of nephritis need be anticipated in these. Of the remainder a few will give a record of recurrences of gross haematuria but without other signs of ill health. It does not appear that these have an unfavourable course. In adults this forms a larger group than in children. A few patients appear to be unwell, but without signs of defective renal secretion, this group would, of course, include cases with poor constitutions who would not have been counted healthy in any circumstances.

There will remain a small residuum of cases—say 5 per cent—with definite evidence of progressing renal deficiency. Can this small but serious group be recognized in the early stages? I believe that this is so, and that these progressive cases are those which in the initial attack cause anxiety by the persistence of definite albuminuria and blood with signs of general ill health, and often by defective men concentration tests. Thus from the onset, or shortly after the onset, these cases with a serious prognosis can be recognized, while in the remainder the prognosis is good even in the presence of persistent or recurrent small amounts of albumin and red cells.

The group with advancing renal defect drifts on to a state of chronic nephritis with increasing blood pressure and blood urea, oedema of face, and finally death in uraemia. It may be difficult to say whether a case is to be regarded as chronic parenchymatous or chronic interstitial nephritis, but in recorded cases interstitial changes are prominent.

Pathogenesis

The pathological changes leading to the renal haemorrhage are still uncertain, and difficult to ascertain, possibly the group contains cases of different aetiology, but, in general, it appears to be intermediate between nephritis and a haemorrhagic state. As a rule the patients do not die, and even the fatalities rarely occur until after the lapse of years. A certain amount of information about the pathology is obtainable from kidneys or portions of kidneys which have been removed at operation. Fahn has described the changes in the acute stages as a "diffuse capillaritis of the glomerular loops," but the changes observed amount to little more than the presence of haemorrhage in some of the glomeruli. Here and there may be a few foci of small round cells in the interstitial tissue, but the tubules and the remainder of the kidney are normal, many of the glomeruli are unaffected, and are sufficient to maintain efficiently the necessary renal functions.

In later stages kidney tissue has been removed principally in two groups of cases. In one group there have been repeated gross haemorrhages without clinical signs of renal insufficiency, and in these the kidney structure is often recorded as normal. In the other group there has been more persistent though less marked haemorrhage, together with evidence of renal defects, in these the kidney tissue presents the changes of chronic nephritis, and, though the exact type is variable, interstitial changes are usually recorded.

Returning to the structure in the acute stages, this may be described as a diffuse glomerulitis. The freedom of the tubules and of the passage from the glomeruli may account for the briskness of the haemorrhage. Similar pathological changes are found in the kidneys in subacute bacterial endocarditis, in which cocci are present in the affected glomeruli, and the lesions are accepted as being the result of bacterial emboli. The condition, however, differs from acute haemorrhagic nephritis in which no bacteria are found in the affected glomeruli, and the urine is practically

always sterile, though this is often so also in endocarditis. Further, acute haemorrhagic nephritis is not uncommon in glandular fever or infective mononucleosis, which is certainly not due to any of the ordinary cocci or bacilli. Nor could bacterial emboli account for the hereditary and familial cases of haemorrhagic nephritis which have been studied by Hurst and others. In subacute bacterial endocarditis the haemorrhage is usually microscopic, and in those cases in which it is gross a definite renal infarct is practically always found at necropsy. It may be definitely decided that acute haemorrhagic nephritis is not due to bacterial emboli.

Many cases occur so directly connected with a frank tonsillitis that it cannot be doubted that they are effects of the same cause. But it is impossible to say whether the mode of action is a nephritis or an increased permeability of the capillaries. If the haematuria is due to the latter cause, haemorrhages would be expected to occur from other parts with a certain degree of frequency. This raises a difficult question. Any case of haematuria in which purpura occurred would certainly not be included in this group in any records. With regard to epistaxis, it is so rarely recorded in the literature that one wonders whether the occurrence of it is not overlooked. Thus acute haemorrhagic nephritis occurs not infrequently in glandular fever, and in such cases it is, in my experience, usually associated with definite epistaxis. Some of the cases of acute haemorrhagic nephritis in children which are recorded in association with cervical adenitis are almost certainly instances of glandular fever. I may mention here that I have never seen a case of glandular fever with haematuria in which any ill effects subsequently developed. I have, however, once seen a child with this condition whose sister was in hospital with acute parenchymatous nephritis, which had commenced at the same time.

The close association of the condition with definite tonsillitis and cervical adenitis, which may occur in epidemics, is an argument that it cannot in general be due to a constitutional haemorrhagic diathesis. Some of the instances of repeated gross haemorrhage may, however, be of this nature. Some of these cases have developed anaemia, although not renal insufficiency, and the kidneys on removal for this reason have proved to be normal, possibly these should be regarded as a separate group. Kidd has shown that an occasional case of "essential haematuria" is due to purpura of the bladder.

The small group in which evidence of renal insufficiency develops show definite renal changes, as stated previously, these cases in general appear unusually grave from the first. The renal changes which occur do not appear to be constant, but it is evident that interstitial changes are often predominant.

This group again raises the question whether the renal changes are the result of persistent injury by haemorrhage or constitute a primary nephritis.

In the family affected with "hereditary, familial, congenital haemorrhagic nephritis" studied by Hurst, one branch suffered from what may be accepted as "acute haemorrhagic nephritis," but another branch tended to develop interstitial nephritis with little haematuria. This suggests that acute haemorrhagic nephritis is a true nephritis, and that changes in the glomeruli are the cause and not the result of the haemorrhage, this would appear to be the most probable explanation of the serious cases, but it is doubtful whether all cases are of the same nature.

Diagnosis and Treatment

In children the diagnosis is usually simple. It is not difficult to exclude other forms of nephritis, and a predisposing factor in or around the throat is present in a high percentage. In adults the diagnosis must not be made until the "surgical" causes of haematuria have been excluded.

In the acute stage simple lines of treatment are sufficient. It is traditional, and for the present advisable, that patients should be kept under treatment, if possible, until red cells are absent from the urine, a trace of albumin may be neglected.

Those cases in which unsatisfactory features are present, as indicated previously, should be treated as for other forms of nephritis.

THE ACTION OF VITAMIN D IN PREVENTING THE SPREAD AND PROMOTING THE ARREST OF CARIES IN CHILDREN

BY
MAY MELLANBY AND C. L. L. PATTISON, M.B., B.S.,
(Pharmacology Department University of Sheffield and
King Edward VII Hospital Sheffield)

In papers published in 1924 and 1926 respectively^{1,2} we recorded investigations showing that the dietetic factors which control the structure of teeth in puppies also influence the initiation and spread of caries in children. Animal experiments^{3,4} had proved that food substances which contained the antirachitic or calcifying vitamin, now called vitamin D, greatly stimulated the calcification of teeth, while cereals, and especially oatmeal, inhibited perfect calcification of the teeth when this vitamin was deficient in the diet. In the investigations on children referred to above we found that diets favourable to calcification limited the initiation and spread of caries, while diets of lower vitamin content, and containing oatmeal, had no such effect. In many cases also diets rich in vitamin D caused "hardening" of teeth in which caries had started, and thus tended to suppress the active carious process. On the other hand, diets with low calcifying properties had no such retarding influence. In both investigations caries was extensive at the beginning, and an attempt was made to group the children in such a way as to start with approximately equal amounts of caries in each group.

In the first series of cases (1924) we attempted in one group to raise the calcifying properties of the ordinary hospital diet by adding extra milk and eggs and by giving cod liver oil. In another group these extras were omitted and oatmeal was added. It may be stated that all the diets were good, and contained a fair amount of milk and other wholesome foods, in fact, from any nutritional standpoint they were probably much better than those eaten by the average child in this country. Table I gives a summary of the results obtained.

TABLE I

Main differences in diet	No. of patients in group	Average No. of teeth per child showing initiation or spread of caries	Average No. of teeth per child in which caries showed hardening	Average No. of teeth per child in which caries showed softening
A1 Abundant fat soluble vitamins and calcium diminished cereal	9	14	15	00
B1 Much less fat soluble vitamins and calcium than A1, more cereal including oatmeal	19	51	07	04
C1 Intermediate between A1 and B1 as regards fat soluble vitamins and calcium and cereal	13	29	10	01

In the second series of cases (1926) an attempt was made to keep the protein, carbohydrate, and fat intake as constant as possible, and to vary only the extras whose effect was being tested. The total energy of the diets, the calcium and phosphorus intake, and the acid-base ratios were also fairly constant. It was not possible to attain absolute accuracy, but a fair equality in most of these respects was brought about. The main variables in the diets A₂, B₂, and C₂ were (a) the fat-soluble vitamins and (b) the anti-calcifying factor of cereals. Fuller details of the diets can be obtained from the original publication (*British Dental Journal*, October 1st, 1926). Below (Table II) is summarized the effect of these diets as regards caries in the children of the different groups. Column 4, describing the "degree" of caries, requires some explanation. Each carious area was numbered according to its extent at the first and last inspection; the figures thus obtained were, of course, quite arbitrary, but were comparable one with the other.

TABLE II

Main differences in diet	No. of children in group	Average No. of teeth per child showing initiation or spread of caries	Average degree of spread of caries per child	Average No. of teeth per child in which caries showed hardening	Average No. of teeth per child in which caries showed softening
A ₂ Abundant fat soluble vitamins	23	18	2.0	2.0	0.3
B ₂ Much less fat-soluble vitamins than A ₂ oatmeal in place of some of bread of A ₂	24	58	6.7	0.0	0.5
C ₂ Intermediate quantity of fat soluble vitamins no oatmeal	24	30	4.0	1.2	0.1

In the present investigation an attempt has been made to vary only one factor in the diet—namely, the vitamin D intake. In the previous investigations cod-liver oil, egg yolk, and extra milk were added to the diet of one group. Now these substances are rich in both vitamin A and vitamin D. Vitamin D is undoubtedly responsible for promoting normal calcification, whether of the developing teeth or of the secondary dentine in erupted teeth, and therefore it might be expected to play an important role in the arrest of dental caries. On the other hand, it is now probable that vitamin A is an anti-infective agent, so that it might also be expected that this vitamin would tend to inhibit the initiation and spread of the infective carious process. Evidence of the susceptibility of animals fed on diets deficient in vitamin A to infective and progeric processes has recently been given by H. N. Green and I. Mellanby.⁵ They found that young rats brought up on diets containing abundant vitamin D, but deficient in vitamin A, died with infective and progeric lesions including infections of the eye, alimentary tract, renal tract, and broncho-pneumonia, and pus formation in the middle ear, nasal sinuses, base of tongue, and many other positions. The limitation of growth which has usually been regarded as the chief characteristic of vitamin A deficiency they suggest may be due to the development of the above mentioned infective conditions in which case this vitamin should no longer be designated the "growth promoting" vitamin, but rather the "anti-infective" vitamin. It seemed likely, therefore, that in the case of the teeth also vitamin A would play a part in the prevention of caries, which is essentially an infective lesion.

Tests are now being made of adding, on the one hand, extra vitamin A, on the other, vitamin D to the constant diets of children and observing the effect of these vitamins respectively on the initiation, spread, and arrest of dental caries. The results so far suggest that vitamin A has little or no effect on the progress of caries, but as the data are not yet sufficiently complete to allow the statement that this vitamin plays no part in preventing or curing dental caries, they will not be recorded here. The tests with vitamin D, however, have given results sufficiently striking to warrant their preliminary publication, and are given below.

The average daily diet of the 21 children in this series (Group A₂) was roughly as follows:

1½ pints milk	1 lb meat (as purchased)
10 oz bread	1 oz bacon (as purchased)
1 oz butter	5 oz potatoes (as purchased)
½ oz cooking fat	5 oz other vegetables (as purchased)
1 oz sugar (including cooking)	
1 oz jam or syrup (including cooking)	½ oz cocoa
½ oz rice, etc	½ egg
	Fruit (four times a week)

The source of vitamin D used was irradiated ergosterol in the form of radiostol. The majority of children in Group A₂ received 2 c cm, some 1 c cm, and some 4 c cm. The investigation lasted twenty-eight weeks, the average number of carious teeth per child at the beginning was 8.8.

The methods of appraising the results were the same as those used in the previous investigations, details of which can be seen in the earlier publications.^{1,2} The month of each child was charted before the feeding test, the

amount and extent and also the "degree" of hardness or softness of each carious area were noted. The main results are summarized in Table III and are compared with the

TABLE III

	Group A ₁	Groups		
		A ₂	B ₂	C ₂
Number of children in group	21	23	24	24
Number of weeks on diet	28	28	25	28
Average age (years) of children at beginning	5.4	8.7	9.0	8.8
Average number of new carious teeth per child at end	0.2	0.5	2.4	0.6
Average number of teeth per child showing increase of old caries	0.8	1.3	3.4	2.4
Average number of teeth per child showing initiation or spread of caries	1.0	1.8	5.8	3.0
Average degree of increase of caries per child	1.1	2.0	6.7	4.0
Average number of teeth per child in which caries showed hardening	3.9	2.0	less than 0.1	1.2
Average number of teeth per child in which caries showed softening	0.0	0.3	0.5	0.1

figures for the second investigation. It must be noted that the results given in this table are not necessarily strictly comparable, partly because of the difference in the average ages of the groups, in Group A₁ the average age was 5½ years, and in Groups A₂, B₂, and C₂ it was nearly 9 years. Now the arrest of caries might be expected to take place more readily in the deciduous teeth of children under 6 years of age, since there is presumably at this time less interference with the pulp tissue of the teeth by the natural processes of root absorption than is the case in the older children.

It is clear from these results that the addition of this one factor—vitamin D—has had a pronounced effect in (a) preventing the initiation of new carious foci, (b) limiting the spread of caries, and (c) apparently arresting the carious process in many cases. The results at first sight seem, indeed, to be better than those obtained in former tests when cod-liver oil, egg yolk, and extra milk were used as the main sources of vitamin D. This is not necessarily the case, however, for it was not possible to gauge exactly the relative strengths of vitamin D in the cod-liver oil, egg yolk, and extra milk and in the radiostol respectively. Moreover, the average age of the children in the third investigation was less than in the previous two. Evidence which supports the view that the better results procured with irradiated ergosterol than with the natural vitamin D-containing foods may be due partly to the age factor, is obtained if children under 6 years of age be chosen from each of the groups and the effect of the diet on caries be compared. The comparison is made in Table IV.

It will be seen that with an average age of under 6 years the addition of vitamin D to the diet of group A₁ gives a result somewhat similar to, though rather better than, that obtained in Groups A₂ and A₃, which had fat-soluble vitamins in the forms of cod-liver oil, extra eggs, and milk, but, as already mentioned, it is not easy to calculate how much vitamin D was present in the diets of Groups A₁ and A₂ in comparison with Group A₃.

The following reports of individual cases give some indications of the observed effect of vitamin D. The first

two cases reacted especially well to the treatment, whereas in the third case the reaction was very slight. It is to be noted that in the first two instances the children were 3½

TABLE IV

(Average Age of Children under 6 Years)

Main differences in diet	No. of children in group	Average No. of teeth per child showing initiation or increase of caries	Average degree of increase of caries per child	Average amount of hardening or arresting of caries per child
A ₃ Institutional diet plus vitamin D (radiostol)	21	1.0	1.1	3.9
A ₁ and A ₂ Abundant fat soluble vitamins	18	1.4	1.7	3.7
B ₁ and B ₂ Much less fat soluble vitamins than A ₁ and A ₂ oatmeal in place of some of bread of A ₁ and A ₂	19	5.0	6.0	0.2
C ₁ and C ₂ Intermediate quantity of fat-soluble vitamins no oatmeal	20	3.3	4.5	1.2

and 4 years old respectively, whereas in the third instance the child was 7½ years old.

Case 1—K. C., aged 3½ years

At the beginning of the test 17 out of 20 teeth were carious, 11 being in a bad condition. The degree of caries was 52. This child received 4 ccm of radiostol in addition to the ordinary institutional diet. After thirty-five weeks there was no extension of old carious areas and no new carious points. 12 teeth which showed active caries at the beginning were at the end of the period in a state of partial or complete arrest (see Fig. 2). 3 teeth which at the beginning showed a tendency to arrest had completely hardened up and only 2 of the teeth showed no signs of arrest during the period. These may, of course be dead teeth, but there appeared to be no spread of caries in them. After thirty-five weeks of diet one tooth in which arrest was taking place was extracted and divided into three parts. One piece was stained with fuchsin and another with carmine and ground sections were made from both. The surface did not stain as in active decay, but was uneven (Fig. 2). In the pulp

FIG. 1.—Showing active caries in a hypoplastic tooth from a dental clinic patient aged 5 years. Surface soft and deeply stained with carmine. Hile or no pigmentation, no secondary dentine. (This figure and Figs. 2 and 3 are photomicrographs (×25) of carmine-stained ground sections of three children's molars.)

chamber, in a region corresponding to the injury there was a mass of secondary dentine. A decalcified portion was sectioned and stained for organisms, and showed these to be still present in patches.

Case 2—N. S., aged 4 years. At the beginning of the test 13 out of 20 teeth were carious, 9 being in a bad condition. The degree of caries was 46. This child received 2 ccm. of radiostol daily in addition to the ordinary institutional diet. After twenty-eight weeks there were no new carious points. 2 teeth showed apparent spread of caries due to the breaking away of the weakened cusps. Using the criteria adopted in these investigations it was found that in 5 of the 13 carious teeth the caries was completely arrested and in the remaining 8 there were definite signs of arrest.

The following case is mentioned as being the main exception in this series for the reaction to the treatment was distinctly poor. This may be due partly to the greater age of the child and partly to the fact that too little irradiated ergosterol was given to allow the effect to be developed in the period of observation.

Case 3—A. K., aged 7½ years. At the beginning of the test 11 out of 21 teeth were carious, 4 deciduous ones being in a bad condition and 3 out of the 4 permanent ones being also affected. The degree of caries was 23. This child received 1 ccm. of radiostol in addition to the ordinary institutional diet. After twenty-nine weeks fresh new points of caries appeared in 2 teeth and some spread of caries was found in 4 teeth. There were 11 degrees of increased caries. Six teeth showed some hardening.

In the whole series of 21 children to whom irradiated ergosterol was given a large proportion of the total increase

and spread of caries took place in Case 3 (A K), and if this patient is eliminated the results of this treatment on the remaining 20 children are exceptionally good. At the beginning of the investigation the 21 children had 185 carious teeth. In all the children at the end of the investigation there were 4 new points of caries, all very small. Of these 4, 2 were in Case 3. In the 185 carious teeth 16 showed some spread of the infective process on the breaking down of the enamel and of these 4 were found in Case 3. In the majority of the teeth the soft and apparently active caries was in the course of arrest and in many cases had actually been arrested, so far as could be ascertained.

The difficulties of an investigation of this type are obvious, and include that of appraising the amount or degree of caries in any tooth. Thus the apparent spread of caries may sometimes be due to the breaking down of a well portion of the enamel, although such cases are classed as actual spread of the infective process. Again, it is often impossible to tell whether a tooth is already dead as the result of caries before the special feeding has begun, and it is probable that the absence of response to the vitamin in some of the teeth is due to this fact.

The question as to the effect of diet on the prevention and arrest of caries in adults is of great importance, but up to the present time only one patient (22 years of age) has been examined and charted carefully before and after treatment by an independent worker. In this case 2 c.m. of radiostol were added daily to an ordinary diet. At the beginning of the period under review all the teeth were present in the mouth there were no fillings, and the only caries present was in the two upper third molars, which were badly affected, and one lower third molar, in which the caries had started. After six months' treatment the upper molars were seen to be definitely hardening, and there was no visible increase in the carious patch in the lower molar. Other cases are being examined.

The facts observed show that arrest of decay is essentially due to the presence of vitamin D in the diet, and that vitamin A (the anti-infective vitamin) possibly plays little or no part in this arrest. Whether, as seems possible, vitamin A is of importance in the general immunity of some mouths to caries cannot at present be stated. In any case, the arrest of caries involves some post-developmental calcification of the teeth, and is possibly due rather to this defensive agent than to the specific agents controlling resistance to infection in the case of other tissues.

It may be pointed out that in the series of children (A) receiving vitamin D no effort was made to limit the

cereal intake of the diet. It has been shown that cereals specifically interfere with tooth calcification just as vitamin D specifically promotes calcification. It is probable that cereals also interfere with the arresting of caries, and that this effect is antagonized by vitamin D. On this point, however, there is but little direct evidence.

The Process of Arrest of Dental Caries

Since the actual process of arrest of dental caries becomes, in consequence of these investigations, largely a problem of nutrition, it may be well to refer to the main changes that occur in the teeth during this process as illustrated in some of the teeth of the subjects of these investigations.

In active caries the surface of the area attacked is usually more or less soft. In the early stages of arrest it tends to harden and may appear rough, later the irregularities are gradually removed, probably mechanically, and the surface becomes still harder and smoother and

more pigmented until finally it is hard, smooth, polished, and pigmented. Caries may, of course, recur in the arrested area when the conditions are again altered. In response to caries, changes, apart from pigmentation, may take place, not only in the primary dentine (Fig. 2), but also in the pulp, the odontoblasts, in an endeavour to protect the living tissues of the pulp, may lay down new dentine—the so-called secondary dentine—to form a protective barrier. When arrest is about to take place it appears that these

processes are generally exaggerated and much well calcified secondary dentine is formed,^{7,8} and finally the bacterial onslaught is prevented. It is, however, more common for the reaction to caries to be poor, so that there is little or no secondary dentine formed, or that formed is poorly calcified and contains many interglobular spaces, and caries spreads. These facts are illustrated in Figs. 1 to 3 which are photomicrographs of carmine stained ground sections. Unfortunately the photomicrographs do not differentiate between the pigmented and stained areas. Fig. 1 shows a tooth with active caries, the surface is irregular, a large area of the dentine is deeply stained, indicating decalcification, and there is no secondary dentine. In Fig. 2 the carious process is being arrested, as is evidenced by the reduced staining power and the slight brownish pigmentation of the dentine and the amount of well calcified secondary dentine. (Note: The carious surface of this tooth felt hard in most parts when examined with a probe.) Fig. 3 shows almost complete arrest of caries. The dentine is unstained, but somewhat pigmented, and there is much well calcified secondary

FIG. 2.—Showing arrested caries in a hypoplastic tooth from Case 1 mentioned in the paper. (Vitamin D was added to the hospital diet for thirty-five weeks prior to the extraction of this tooth.) The surface of the tooth was hard when tested with a fairly sharp probe, but was rough in places and had not the polished appearance of long-standing arrest. A few small areas are stained with carmine and there is some general brownish pigmentation. There is much well calcified secondary dentine coinciding with the carious area.

FIG. 3.—Showing arrested caries in a hypoplastic tooth from a hospital patient aged 4 years who had prior to the extraction received cod liver oil for three years. The surface was hard and smooth and appeared partly polished, no staining, slight brownish pigmentation, much well formed secondary dentine. E=Enamel, D=dentine, P=pulp, IS=interglobular spaces, 2D=secondary dentine, Pg=pigmentation, Cm=carmine.

face is irregular, a large area of the dentine is deeply stained, indicating decalcification, and there is no secondary dentine. In Fig. 2 the carious process is being arrested, as is evidenced by the reduced staining power and the slight brownish pigmentation of the dentine and the amount of well calcified secondary dentine. (Note: The carious surface of this tooth felt hard in most parts when examined with a probe.) Fig. 3 shows almost complete arrest of caries. The dentine is unstained, but somewhat pigmented, and there is much well calcified secondary

dentine. It is interesting to note that even in sections of teeth in which caries appears to be completely arrested the dentinal tubules may contain micro-organisms. These, however, are apparently inactive. For instance, some Gram-positive bacteria were found in the dentinal tubules of the teeth ground sections of which are seen in Figs 2 and 3.

The production of secondary dentine in puppies by artificial stimuli has been related to the intake of vitamin D.¹ With an abundance of this vitamin much well calcified secondary dentine is formed as the result of a given stimulus, whereas with little of the vitamin there is little or no reaction. The arrest of caries in children obtained in the present investigation as the result of giving abundant vitamin D in the diet is, therefore, just what would be expected on the basis of the animal experiments.

That other factors play a part in the arrest of caries seems certain but at present little is known concerning these. It has been shown by one of us² that calcifying diets which tend to assist the arrest of caries also result in a high calcium content of saliva, which may be of significance.

Summary

In a batch of 21 children whose average age was about 5½ years the addition of vitamin D in the form of

irradiated ergosterol (radiostol) checked the initiation of new carious points, diminished the spread of old carious points, and arrested the infective process in many carious teeth.

This investigation corroborates those previously made, in which it was found that the carious process in the teeth of children could often be inhibited by increasing the intake of fat-soluble vitamins by the addition to the diet of cod liver oil, egg yolk, and extra milk. The present work shows that vitamin D is a most powerful agent in these inhibitory processes.

Our thanks are due to the Medical Research Council and the Dental Board of the United Kingdom for their financial support of these investigations, and to the British Drug Houses, Ltd. for preparing and supplying the radiostol and the vitamin A oil used.

THE UTILITY OF STREPTOCOCCAL VACCINES IN THE TREATMENT OF PUERPERAL SEPSIS

By

RICHARD R. ARMSTRONG, M.D., F.R.C.P.,

AND

WILFRED SHAW, F.R.C.S.

THE following paper describes an investigation carried out (1) on clinical lines, (2) by laboratory experiments on animals, to decide the utility of vaccines in the treatment of puerperal sepsis.

Clinical Investigation

It is generally accepted that the *Streptococcus pyogenes haemolyticus* is by far the commonest cause of puerperal septicaemia. The majority of morbid puerperia are also due to this organism. At St Bartholomew's Hospital, London, trust has been placed, during some years past, in the use of *Streptococcus pyogenes* vaccine, both as a prophylactic and for treatment in the severer forms of streptococcal infection, including puerperal fever. Vaccine "sensitized" by suspension in Pasteur Institute anti-streptococcal immunizing serum has been used. The mere fact that there has been constant demand over a long period of years for this vaccine implies a belief in its therapeutic value. But nothing is more difficult than to estimate the worth of a particular method of treatment in an infective disease naturally liable to spontaneous recovery.

The conditions under which the maternity and lying-in practice of St Bartholomew's Hospital extern midwifery district are conducted favoured a large scale inquiry designed to test the value of vaccination as a preventive of morbid complications. Every woman has been delivered in her own home. During the first month of our inquiry each patient received a dose of sensitized killed *Streptococcus pyogenes* vaccine, containing 250 million organisms, on the day of delivery. If the patient's temperature rose, 500 million vaccine was given, followed the next day by 1,000 million vaccine, this latter dose being continued daily till the temperature fell. During the second month no prophylactic dose was given, but pyrexia was treated by 250 million vaccine on the day of onset, 500 million the next day, and then 1,000 million vaccine daily till the temperature fell. During the third month vaccine was not given in any circumstances, so that women confined during this month served as controls to the other cases. The same routine was observed in the following quarter, and so the changes were rung until, in the course of two years, the results of two thousand cases were available for analysis.

The women were visited and treated in their own homes by such means as were available in a district of the poorest class. The only technical refinement has been the consistent use by the midwifery clerks of sterilized rubber gloves and the employment at each case of a "drum" containing the following sterilized dressings, etc.: a sterilized gown, four small towels, two large pieces of wool six small surgical wool swabs, two long strips of folded gauze, 1½ yards in length (for plugging the cervix if required), six gauze eye swabs, this in addition to the fully equipped midwifery bag such as is in universal use.

Such apparatus betokens more than an attempt at surgical cleanliness. It is to be considered an outward and visible sign of inward and spiritual grace, a recognition by the midwifery student even in his novitiate, of the essential need to avoid contamination by employing cleanliness, care, and conservatism in the management of labour. We believe it is to this that the satisfactory results as regards morbidity and fatalities are due.

The vaccines used have been described above as "sensitized." Sensitization implies the conjugation of bacteria with specific antibodies contained in the homologous immunizing serum. It is doubtful whether the streptococcal vaccines used in the inquiry were truly sensitized in this sense. A suspension of pneumococci or typhoid bacilli, in contact with their corresponding antiserum, is agglutinated and precipitated in a conglobulum consisting of bacteria surrounded by a gelatinous capsule, this may be stained and clearly seen under the microscope. Such a vaccine is actively chemotactic, and is rapidly ingested by leucocytes. The *Streptococcus pyogenes* vaccine supplied for use did not behave in this manner, and it is therefore doubtful if it were truly "sensitized." Experiments described by one of us¹ seem to prove that, at least in the case of the pneumococci, sensitized vaccines are less rapid and less efficient antigens than "raw" vaccines. It is probable, therefore, that nothing was lost to treatment by the inoculation of simple vaccine. In any event it must be pointed out that the investigation here described was not so much a progressive and reasoned attempt to establish new treatment as a test of the validity of existing practice and beliefs.

In classifying the cases the British Medical Association standard of "morbidity" has been adopted—namely, a rise of temperature from any cause whatever, not necessarily streptococcal infection, to 100.4° F., on two occasions at least between the second and tenth days of the lying-in period. By "clinically septic" is meant the occurrence of offensive lochia, subinvolution of the uterus and characteristic fever. The temperature shows a rise on the third day, a maximum on the fifth day, and fever persisting for an average of five days. "Septicaemia" indicates the severest form of infection with the demonstration of *Streptococcus pyogenes* in blood culture.

Results

The cases may be grouped as follows, it is to be understood that the category "morbid" also includes all the clinically septic cases and any case of septicaemia.

GROUP A—250 million *S. pyogenes* vaccine on day of delivery in any event followed if a rise of temperature occurred by a further dose of 500 million the next day 1 000 million this dose being continued daily until the temperature fell.

Date	No of Cases	Morbid	Clinically Septic	Septicaemia
July 1925	81	5	3	—
October 1925	74	5	2	1
January 1926	59	4	3	—
May 1926	81	1	1	—
July 1926	75	2	2	—
October 1926	85	5	5	—
January 1927	78	4	3	—
April 1927	63	0	0	—
July 1927	69	1	0	—
Total	668	27	19	1

Percentage Morbid 4.04 Clinically septic 2.8

GROUP B—No prophylactic dose on day of delivery. If a rise of temperature occurred 250 million *S. pyogenes* vaccine was given on the day of onset followed by 500 million the next day and by 1 000 million on each succeeding day till the temperature fell.

Date	No of Cases	Morbid	Clinically Septic	Septicaemia
August 1925	76	6	4	—
November 1925	71	2	1	—
February 1926	79	4	3	—
April 1926	69	2	2	1
August 1926	61	2	2	—
November 1926	60	2	2	—
March 1927	68	2	2	1 death
May 1927	56	3	3	—
August 1927	75	3	2	—
Total	618	26	21	2

Percentage Morbid 4.20 Clinically septic 3.69

GROUP C—No vaccine in any circumstances whether the temperature rose or not.

Date	No of Cases	Morbid	Clinically Septic	Septicaemia
September 1925	72	6	3	—
December 1925	79	2	2	1
March 1926	69	3	2	—
June 1926	69	2	2	—
September 1926	71	1	1	—
December 1926	76	3	1	—
February 1927	67	1	1	—
June 1927	59	3	3	—
September 1927	54	2	1	—
October 1927	53	1	0	—
November 1927	54	4	3	—
Total	721	28	19	1

Percentage Morbid 3.89 Clinically septic 2.6

A comparison of the summaries at the foot of each table makes clear that there is little to choose between the three groups of cases. The morbidity rate is low in each group, and, as it chanced, lowest in the unvaccinated. In fact,

had this all important control group been omitted, it would have been tempting to argue that prophylactic vaccination had proved highly beneficial.

The experience during the whole period may be summarized briefly. In all 2,007 cases were delivered, 81, or 4 per cent, became morbid, and of these 61, or 3 per cent, were recorded as clinically septic also. There were 4 cases of septicaemia, one of which proved fatal. In addition, one fatal case of *ictus gravis gravidarum* and one of pneumococcal peritonitis occurred, making a total of three deaths in all.

Operations and Morbidity

A study of the individual case records, particular details of which there is no space to include, makes the close correlation of morbid temperatures with operations abundantly clear. The following operations were performed:

Replacement of cord	1
Bipolar version	2
Internal version	1
Episiotomy	1
Cesarean	2
Manual removal of placenta	13
Forceps delivery	40
Total	60

The two latter operations were most often associated with morbidity, manual removal in particular.

The total morbidity among the operation cases was 18, or 31 per cent, as compared with a gross morbidity rate of only 4 per cent over the whole series, or, deducting operation cases, a net rate of 3.23 per cent. Operative intervention, therefore, increased the rate of sepsis ten-fold. It will be noted that the forceps rate was only 2 per cent.

The low incidence of cases requiring operation is to be attributed in part to conservative tradition and practice in the district. In the main it must be recognized to be due to careful ante-natal supervision. As a result, cases which would inevitably have proved complicated have been eliminated from among the women treated in their own homes. Thus the conditions perceived and postulated by James Young, of Edinburgh in his admirable survey of the problem of puerperal sepsis, published in the *British Medical Journal* (June 9th, 1928, p. 967), have been to some extent realized. On the one hand there is convincing proof of the close causal interrelationship of morbidity and operative intervention—inevitable, apparently, no matter what patience be exercised in confinement to avoid forceps delivery. On the other hand ante-natal supervision has fulfilled its proper function in segregating cases likely to be complicated, for appropriate institutional treatment in the best possible surroundings.

The day of onset of pyrexia during the puerperium is of interest.

Day of Puerperium	No of Cases	Day of Puerperium	No of Cases
1	6	6	2
2	14	7	3
3	21	8	1
4	13	9	4
5	7	10	0

Thus in one third of the febrile cases a rise of temperature occurred on the third day, and in two thirds from the second to the fourth day inclusive.

A bacteriological study by one of us of the uterine flora day by day after delivery, the results of which are in course of publication, indicates that the uterus becomes invaded very early in the puerperium by bacteria from contiguous surfaces. This growth rapidly increases from the third to the fifth day, after which it diminishes, practically to disappear by the tenth day. The frequency of raised temperature on the third day of the puerperium therefore receives explanation.

Literature

Turning now to results published elsewhere, we are largely indebted to the chapter by Sigwart in the recently published *Biologie und Pathologie des Weibes* (Berlin, 1927, vol. 8, Part 1, p. 719 et seq.) for references to results of the use of streptococcal vaccine in the prevention and treatment of puerperal sepsis. The published observations

fall under two headings (1) large scale experiments (2) treatment of relatively small numbers of women in the wards of lying in hospitals.

In the former category Tolten (1917) inoculated some 1 600 women shortly before labour and found that the larger the dose of vaccine administered the lower the morbidity rate. No control group was studied. Thus

No. of Cases	Dose of Vaccine (millions)	Morbidity (per cent)
819	25.50	16.0
433	100	13.3
300	250	10.6
126	500	7.1

The methods employed by Louros (1923) have served as a model for several investigators. Louros gave 250 million polyvalent streptococcal vaccine twenty days before confinement was to be expected, and a further dose of 500 million vaccine ten days before. The concurrence of a negative phase, following vaccination, with the time of delivery was thus avoided and active immunity was supposedly established. Of a group of 151 women so treated, 33 sustained complications in subsequent childbirth, only in one case did the temperature rise above 104° F. But all the women were carefully watched and treated in the maternity clinic before and during their labours and puerperium, the low incidence of sepsis might as well have been ascribed to this as to the vaccine.

In another series of 3,215 births and abortions 522 cases were immunized, some actively and some both actively by vaccines and passively by administration of anti-streptococcal serum before and during labour. All of these cases were either febrile or, being complicated, were likely to develop fever, 163 actually ran temperatures, 4 of these were cases of septicaemia and 4 deaths occurred from various causes, not necessarily the result of streptococcal infection.

Maroudis (1923) applied Louros's methods in the maternity clinic at Athens. Despite adverse conditions and overcrowding, the results among vaccinated women were better than among the untreated.

Of 1 229 vaccinated women 367 received two doses of vaccine before labour, and 862 received 500 million vaccine and anti-streptococcal serum during labour. Among these women there was no death from streptococcal infection and only 2 had local streptococcal infections. Among 786 untreated women there were 7 deaths and 8 suffered from local infections.

In the second category, treatment of groups of women in hospitals, the published descriptions scarcely merit individual mention, for the results are equally divided for and against vaccination. No results are claimed in highly virulent infection, unhappily, in such cases death invariably supervenes before time has elapsed sufficiently for the dose of vaccine to have established adequate protection. Indeed, a woman surviving long enough to be fully treated by Louros's standard might be expected to recover unaided.

Summary of Clinical Evidence

The clinical evidence, then, in favour of the use of streptococcal vaccine, if not negative, is indefinite, whether the vaccines be used in prophylaxis or for treatment. In making this assertion we do not presume to express an opinion on the efficacy of bacterial vaccines in general. Amongst experienced clinicians the feeling that vaccines are of service is too strong for the subject to be lightly dismissed. Nevertheless, in our opinion, the scale, both clinical and experimental, on which our observations have been carried out justifies our conclusion.

Non-specific Protein Therapy

Against the claim that the alleged protective effects exercised by streptococcal vaccines in puerperal sepsis are specific is the fact that similar results have been obtained by the use of heterologous vaccine such as *B. coli*. In fact Louros himself suggests that the vaccine acts by protein shock.

It is not opportune to discuss here how far non-specific vaccine therapy is of value, whether the reagent be administered in homeopathic doses of a few million organisms or in masses sufficient to produce protein shock. Such

observations as favour vaccine treatment of puerperal sepsis tend rather in the direction of non-specific protein therapy—the larger the dose of foreign protein administered and the more severe the “shock” produced, the greater the apparent effect on the course of the disease. Under the heading of protein therapy, treatment by “colloidal” metals (for example, silver) must undoubtedly be included, as the effect produced must likewise be attributed to the protective colloid rather than to the metal component. The phenomena of shock and recovery are undoubtedly in some way bound up with leucocytic activity.

Experiments with Animals

It is very remarkable that so common an organism as the *Streptococcus pyogenes* should have baffled experimental investigation. At first sight the efficacy of streptococcal vaccines would appear readily ascertainable by experiment with animals, but this is not the case in practice. The susceptibility of laboratory animals—rabbits, rats, and mice—to streptococcal infection is not only low, but varies greatly, furthermore, difficulties constantly arise owing to change and depreciation in the virulence of streptococcus strains.

The method of intradermal inoculation of the shaven back of rabbits, first described by Birkbueg² in 1925, but initiated independently by one of us,³ has proved, within limits, of value in studying antistreptococcal immunity. Unfortunately, considerable doubt has been thrown on much of Birkbueg's work and his results have not been successfully repeated in this country.

Intradermal inoculation of shaven rabbits with a culture of a recently isolated strain of *S. pyogenes*, the virulence of which has been well maintained by animal passage, is followed by the appearance of local lesions proportionate in severity to the size of dose and resistance of the animal. Three doses—1/10 c.c., 1/100 c.c., and 1/1,000 c.c.—of a sixteen-hour broth culture, 1 c.c. of which is fatal to a mouse within twenty-four hours, are inoculated alongside each other. The characteristic lesion is a local erysipeloid patch, sometimes also surrounded by a bright scarlet erythema. Local suppuration usually follows, or actual necrosis of tissue may occur with formation of a deep ulcer.

In resistant animals the lesions may not progress beyond the stage of cellular infiltration. Almost without exception lesions are fully developed by the fifth day, after which recovery sets in and is complete by the tenth day, in the sense that streptococci disappear and active inflammation ceases, although mechanical damage may persist and heal but slowly. It seems reasonable to conclude that, taking a batch of rabbits of about the same weight and age, the severity of the lesions may be accepted as an index of the balance between virulence of infection and vigour of defence.

The experiments were originally planned to determine the prophylactic value of the products of streptococcal growth, “toxins” as well as vaccines. Two rabbits were immunized with each of the prophylactic agents under test, a pair was likewise inoculated with living virulent streptococcus culture, a pair was reserved as blank control. In a long series of experiments three intradermal inoculations of the homologous strain of streptococcus in living culture were administered, as described, at intervals of from five to ten days after completion of the prophylactic course. The degree of immunity possessed by each animal was apparent on comparing the lesions on the third and successive days, a survey of the whole batch enabled a just estimate to be formed of the significance of each experiment.

In general terms, the method failed to differentiate the relative prophylactic efficiency of broth filtrates (toxin) and vaccine, it was often a matter of difficulty to decide whether unprotected animals or those which had received killed vaccines were more susceptible. There was no ambiguity, however, in deciding the merits of living culture, as the animals so protected were completely resistant to subsequent infection in every instance. Laboratory experiments, therefore, support the clinical evidence that streptococcal vaccines are of doubtful value as a safeguard against living virulent streptococci.

Conclusion

Summarizing the position, morbidity in the puerperium is in the main due to a single cause, the *Streptococcus pyogenes*, the failure of vaccines, a specific means of treatment, is, therefore, the more disappointing.

It appears that all but a few of our morbid cases recovered spontaneously. This being so, the conclusion follows that special remedies, such as vaccines, are of subsidiary importance in the prevention of sepsis as compared with conservative and aseptic midwifery. Puerperal sepsis, being a specific disease, must be recognized as a definite clinical process to be treated like any other infections or contagious malady.

We are particularly indebted to Dr. Malcolm Donaldson for assistance and advice throughout the inquiry. The inauguration of the experiment on the extern district and the details of treatment were due in the first instance to him, and were carried out under his direction. To Donaldson also is due the introduction of the systematic use of sterile dressings and towels on the district and insistence on conservative methods in the management of labour, his name in particular must therefore be associated with this paper. The extern midwifery department is grateful to Dr. Mervyn Gordon consulting bacteriologist to the hospital for large supplies of vaccine and for much helpful advice on its application.

Acknowledgement is due to the Medical Research Council for assistance in the conduct of the experimental side of the inquiry.

OBSERVATIONS ON BREAST-FEEDING

BY

H. W. POOLER, M.B.,

MEDICAL OFFICER TO INFANT WELFARE CENTRES, DERBYSHIRE
COUNTY COUNCIL

It is customary in this Branch for the incoming president to deliver an address or read a paper, a task which I, as a general practitioner, have viewed with some dismay. I have chosen, however, a subject which I think is interesting to all general practitioners, and particularly to

CHART 1.—Showing superiority of breast feeding over artificial feeding in good and bad conditions of home. A1, Breast fed by careful mothers. A2, Breast fed by careless mothers. A3 Artificially fed by careful mothers. A2, Artificially fed by careless mothers.

TABLE I.—Showing the average weights at 1 year of infants grouped according to the income of individual members of the family after rent is paid

	Average weekly income up to—						Over 5s.

those who, like myself, have been engaged in the work of infant welfare for many years. To such the question of breast-feeding is paramount, whether we consider it from the point of view of the mortality or well being of the infant, or even from that of the comfort and happiness of its parents. Chart 1 and Table I illustrate this, the type

* Being the presidential address delivered to the Midland Branch on July 13th 1928 (abridged)

of home or of mother, or the wage of the father, makes no difference to the comparative results. Breast-feeding, then, being of prime importance, why is it that so many women do not continue to suckle for the necessary period? I propose to discuss a few of the reasons which so often lead to the abandonment of breast-feeding.

The mammary secretion depends almost wholly on one vital factor—the efficiency of the suction stimulus of the infant, acting probably through the sympathetic system, with a centre in the medulla. As the milk is formed it accumulates in the enlarged galactophorous ducts, and after the tension has reached a certain point further secretion is inhibited. If the ducts are emptied a new secretion begins. The emptying of the ducts seems to constitute the normal physiological stimulus to the gland cells, and any condition in mother or child interfering with this stimulus will cause difficulty in the establishment and maintenance of breast-feeding. In the case of the child interference with suction may be due to

1 *Immaturity or immaturity or some cerebral injury at birth*, often resulting in somnolence. In some of these infants suction is ill controlled and inco-ordinated, or the act of swallowing may be bungled, so that the milk escapes by the mouth or sets up fits of coughing. Apart from actual injury, infants who have suffered severely at birth from the effects of a difficult labour are apt to be inert, lax, and feeble in suction for a few weeks.

2 *Various infective disorders*, such as sepsis neonatorum, icterus, eclampsia, and haemorrhagic disease, which cause loss of appetite and refusal to suck.

3 *Indigestion*, often brought about by injudicious purgation or irregular or too frequent feeds, is usually of a simple type due to too frequent feeding. It has been stated that there may also be a fat indigestion, brought about by the ingestion of excess fat in the frequent small feeds, the child is being fed practically on 'strippings' always carrying a high percentage of fat. I think, however, this is extremely doubtful. Some of the wet-nurses at the Paris Maternité frequently give from 30 to 40 feeds a day, and the infants under their care do not appear to suffer from fat indigestion at all.

4 *Morbid conditions of the child's nose, mouth, and upper air passage*, such as thrush, Bednar's aphthae, nasal catarrh, adenoids, bronchitis, cleft palate, etc.

5 *Constitutional dyspepsia*, a constitutional condition characterized by indigestion from the outset.

6 *A neurotic temperament*.

In the case of the mother there may be

7 *Local conditions*, such as depression, excoriation or cracking of the nipples, and abscess of the breast.

8 *General conditions*, such as malnutrition from deficient nourishment, carious teeth, dyspepsia, etc., and

9 *Psychological causes*, as anxiety, excitement, over-exertion, want of sleep, etc. Budin describes a serious setback to three or four infants in the Paris Maternité due to a violent fit of passion in their wet nurse.

Many of the difficulties I have enumerated can be obviated by simple hygiene of the breasts before or after delivery and other troubles, and their treatment, are matters of everyday experience. I do not propose to dwell further on these, but rather to discuss the more serious conditions which interfere with the establishment and maintenance of lactation, and, incidentally, certain theories and speculations of my own concerning some of them.

CONDITIONS AFFECTING THE MOTHER

Delayed Lactation

In some cases the full supply of milk may not be forthcoming for three or four days after labour, and may even be postponed for three weeks. If there is delay this is one of our most difficult periods, the mother is getting very nervous about her child, and must be encouraged and reassured in every possible way. It is well to avoid any form of artificial feeding. If this is not possible, a little boiled water sweetened with saccharine, or an ounce of whey, may be given for the first three days. We should, however, strictly limit the amount—the child must be kept hungry till lactation is established.

Underfeeding of the Mother

Underfeeding of the nursing mother has, I am sure, some effect, not perhaps on the actual development of lactation, but certainly on its efficiency. I have had the

opportunity of observing a very large number of cases of breast feeding by women distinctly suffering from poverty and underfeeding, and I submit for consideration a chart and figures which are the result of my observations

CHART 2.—Showing the average weights of breast fed infants grouped according to the financial position of the parents (a) in poverty, average number in family—5.7 average income per person less rent—2s. 1d. (b) not in poverty, average number in family—3.68 average income per person less rent—4s. 11½d.

TABLE II.—Showing condition of breast fed infants at 1 year grouped according to wage of fathers

	Wage less than £1 weekly	Wage over £1 weekly
Good	53 per cent	79 per cent
Fair	29 "	18 "
Puny	12 "	3 "

It is evident that something has interfered with the normal growth of the breast-fed baby in poverty, and I suggest that it is some deficiency in the quantity or quality, or both, of the mother's milk

In a paper published by Pritchard on "The food requirements of infants," he gives the figures of a large number of observations on test feeds conducted by himself and other English and Continental observers, and, commenting on them, he says

"Making allowance for all sources of error, I find that the average consumption of breast milk by the slum infant is about 33 per cent less than the estimates given by German observers for institutional infants or than the estimates I have myself made in the case of infants in well-to-do families"

Subsequently, in a paper read by me at the National Conference on Infant Mortality in 1914, on "The effect of income on nursing capacity and infant growth," I produced further figures obtained from my own infant welfare centre, and other sources in Birmingham, corroborating this view, and in addition emphasizing the fact that, generally speaking, the gain in weight of the child varied with the amount of milk taken

No doubt, in large measure, as pointed out by Pritchard, the smaller amount of milk given by the consultation or slum mother is an indication of the smaller demands of her child, but may there not be other factors at work? Mental shocks, great emotion, intense anxiety, may not only diminish the milk flow, but absolutely stop it. Budin has reported such a case in his book *The Nursing A*. British Government report prepared by the Intelligence Department in 1918 on "Infant welfare in Germany during the war" states that "in many instances mental distress deprived mothers of the power to feed their infants at the breast"

I have myself seen a case in which the shock caused by the accidental death of her husband completely inhibited a woman's milk production. Is it too much to suppose that, if great emotion can completely inhibit the minor but long-continued worries and anxieties of the working woman may diminish the supply? And if we admit the effect of mental strain, can we exclude, as another factor, the physical strain undergone by a nursing mother who is being constantly underfed?

Evidence as to the improvement in the quality of their milk which followed the proper feeding of nursing mothers is afforded by the observations of Duncan and Elgood Turner, working independently in Birmingham. They analysed numerous samples of milk from poverty-stricken women who were being given one substantial meal five or six days a

week, and they agree that "while the mothers were being fed the percentage of fat in nearly all cases increased, and diminished when the meals were discontinued the baby's weight curve improved as the fat content increased"

In similar circumstances I investigated 23 cases in Birmingham, and found that there was an average improvement of 1.16 oz weekly, as compared with the average gain before dinners were supplied, or something like 3 lb if the improvement was maintained for ten months. A chart illustrating this, in two cases, is shown below, the improvement in the curves while meals were being given to the nursing mothers is evident

CHART 3.—Effect on infant weight curves of feeding nursing mothers

CONDITIONS AFFECTING THE CHILD

Irregularity or Somnolence from Prematurity, Immaturity, Twin Birth, Toxaemia, etc

Regular three-hourly breast-feeding will probably prove successful in a week or two. In these cases, as in all in which the breast is not completely emptied by the child, the breasts should be emptied by expression, and the resultant milk fed to the infant, to leave milk in the breasts is to cause cessation of function. If this treatment is not successful the weanling may be fed by a foster-mother, while her more robust child is suckled from the poorly yielding breast, or a robust child and the weanling can be fed simultaneously by the mother herself, the suction of the robust infant at one breast will induce an easy flow from the other into the mouth of the weanling. We must avoid artificial feeding. Even mixed feeding will eventually teach the child to shirk the comparatively hard work implied in breast-suction.

For cleft palate a suitable obturator fitting on to the nipple can be obtained. Adenoids should be removed if interfering with suction, and nasal catarrh treated by instillation of warm alkaline lotion (sodium bicarbonate 1 per cent, borax 1 per cent) from an ordinary eye dropper.

Congenital Dyspepsia

In some children indigestion is evident almost from the first, as shown by green stools, colic, vomiting, abdominal rigidity, and flatulence. We are told by the friends that "the milk does not suit," or that it is "too windy." These cases, which I have called "congenital dyspepsia," have been described by Czerny as manifestations of the status lymphaticus, and he says that they occur in two groups—one composed of infants who are weak, puny, and complaining, in whom there may be no growth for weeks, though they are fed at quite proper intervals and there is an ample milk supply. The other group has an entirely different aspect. The child grows rapidly, and becomes fat, flabby, and pasty, it is subject to seborrhoea and other disorders of the skin, and to affections of the mucous membranes, such as nasopharyngeal catarrh, causing nasal obstruction, which, together with the intercurrent dyspepsia, is liable to lead, sooner or later, to artificial feeding. It seems to me somewhat difficult to believe that two such radically different pictures should belong to one and the same diathesis, but the practical point is that both types suffer from this obstinate indigestion, and that all these infants must be kept on the breast for at least three months. No other food is to be thought of.

In the case of the fat, pasty child it is well to limit the amount of milk taken by shortening the time at the breast to eight to ten minutes, and to give from 1 to 2 ounces of barley water before the feed, as advocated by Cameron. We have to bear in mind that the loss of appetite caused

by the indigestion will impair the efficiency of the suction stimulus, with consequent diminution, and possible cessation, of the breast function. The breasts, therefore, should be emptied as completely as possible by pumping or expression after the child has finished its feed.

The Neurotic Child

Of all difficult problems perhaps the most difficult is that of the neurotic child. It has been stated that 50 or 60 per cent of the early failures to obtain breast-feeding are in the case of children of this type. Let me describe a typical case.

The child was the son of a nervous, excitable woman whose only previous son had died in infancy, her youngest daughter was 13 years old. She was intensely anxious to have a son, and to nurse and rear him when he came. From the first things went wrong. Lactation was late in establishment and the mother became almost frantic with anxiety. When I saw the child he was already infected with his mother's excitement; he was restless, sleepless, and constantly crying. His expression was anxious, he was tense and rigid and his fists were clenched. If asleep the least noise would wake him with a start, and the crying would begin afresh. Put to the breast he would suck greedily, almost fiercely, for a minute or two and then relinquish the nipple and begin crying again. The mother became absolutely worn out; the inco-ordinate, inefficient suction was causing rapid diminution of the milk while on the other hand the constant restless movements and consequent heat loss of the child were causing a demand for an increased supply—a vicious circle was established and the milk available was clearly insufficient. With all this there was frequent vomiting of a character to suggest at first sight a pyloric stenosis. About 7 lb at birth, at 2 months old the child weighed 7½ lb. It had been taken off the breast at 4 weeks and many things had been tried since without success. The mother would not consent to a wet nurse. Without my knowledge he was taken to a local children's hospital and there it was suggested that an operation should be performed and the parents were given twenty-four hours in which to think it over. The father saw me and I told him that no operation was necessary and that "all the child wanted was mother's milk." I knew that a wet nurse was available if they were willing to have her. They consented to try it and the child had its first good meal for nearly two months and slept soundly for ten hours. After that he never looked back. He was wet-nursed for three months and at 5 months went on to dried milk without any trouble.

CHART 4

The weight curve of this child is shown on the chart as A. The other curve (B) is that of another similar case.

A wet-nurse, however, should be looked upon as a last resort, for it may be possible to restore the child to its own mother's breast by the method described by Cameron. He says that such children must be isolated from their mothers except at feeding times, since the nervous upset of mother and child is acting and reacting. They should be applied to the breast, on a pillow to avoid disturbance, while quiet and drowsy. If this be impossible, he gives one grain of chloral and one grain of potassium bromide before each feed, in ten minutes the child should be asleep and can then be effectively nursed. Such treatment can be kept up for weeks, if necessary. As further measures he advises hot packs, prolonged hot baths, and a "strait waistcoat," in the shape of a very tight shirt.

Wet nursing

I have made frequent references to the value of wet-nursing in difficult cases, but even this has its own difficulties. The mother is generally very reluctant to consent

to this procedure, it is often difficult to find a suitable wet nurse able and willing to leave her own home and go into the house of a stranger, the necessary physical examination of the proposed nurse takes time, and some times leads to trouble, and, in working-class households, the extra expense is a matter of consequence. Moreover, I know of no place in the provinces to which we can apply for a wet-nurse with much hope of success. Recently, however, I have had a very striking and interesting experience.

I managed to obtain a wet nurse for a baby with severe indigestion the mother having been unable to suckle for reasons into which I need not enter. The weanling was 4 months old, the foster mother's baby was 9 months. I do not regard the difference in age as of much consequence. It was arranged that the foster mother should be sent for at 8 o'clock every morning and leave for home at 8 p.m., any feed required between these hours to be artificial. We found, however, that the weanling would not suck, though there was an ample supply of freely flowing milk from well-formed nipples. However, I taught the women to express the milk and feed it to the baby from a bottle. They were quite successful and obtained 3 ounces for each meal. Soon they began to find that they could express much more than the infant could take and eventually could obtain over 12 ounces from one breast at the first expression about 9 a.m. The foster mother had avoided nursing her own baby from that breast through the night. After consulting me, they arranged to obtain this amount each morning and store it for use during the day, and the wet nurse then went home.

Here was a problem vastly simplified—the problem of how to wet-nurse a baby five miles away without the nurse being away from her own home all day long. I have looked up all the literature in my possession, but cannot find any reference to the maximum amount to be obtained from a woman's breasts at one sitting. Bindin's wet-nurses at the Materne have given from 50 to 74 ounces per diem divided up into thirty-four to forty feeds, but he does not say what was the greatest amount taken at one feed or pumping.

Hachner reports a test feed of 7 ounces (average) during the seventh month, and Forsyth a maximum feed of 6½ ounces, on one occasion, during the seventh week, both of these were private cases and, presumably, the milk was obtained from one breast only. It would appear, therefore, that it should not be difficult at any time to obtain almost a full day's supply from both breasts of a wet-nurse in an early morning expression. Would, however, milk obtained thus in bulk be deficient in fat? I think it quite probable. On the other hand, since the child to be fed in this way is probably a dyspeptic, a slight deficiency in fat might be rather an advantage than otherwise.

Too Frequent Feeding

Too frequent feeding, especially if irregular, is, I am sure, a frequent cause of failure after the milk has been well established. It might be thought that this is due, partly at any rate, to maternal exhaustion, but Bindin's experiences at the Paris Materne amply disprove any such suggestion. As already pointed out, at this institution wet-nurses can give as many as thirty-five to forty feeds daily and still continue to afford an ample supply. Rather, I think, it is due to loss of appetite in the child and the consequent deficient suction—a loss of appetite caused by indigestion. It is surprising how many infants are still being fed, at least in the first few weeks, two hourly, in spite of all our teaching. In a series of over 500 cases of breast-feeding analysed by me of babies born in the last three years no less than 57 per cent were being fed two-hourly in the first two months, and of these 19 per cent ceased breast-feeding in the first month, as against 7 per cent only of those fed three-hourly. At six weeks 74.5 per cent of the two-hourly group and 87.2 per cent of the three-hourly group were still entirely on the breast.

Leven and Barrett found that in normal infants the evacuation of milk from the stomach, as shown by x-ray photographs, took a minimum of one and three-quarter hours from the time the infant relinquished the nipple, and that in the case of atrophied or dyspeptic infants it might take as much as three hours. Curiously enough, the time taken was about the same for all forms of milk,

and whether diluted or undiluted. They concluded that the minimum interval between feeds must be three hours.

Here is a chart, taken from an article by Dr Harold Waller, which illustrates the effect on milk production of too frequent feeding. The child was an inveterate screamer and was constantly being fed in the hope of achieving quiet. Note the poor weight curve and the

TEST MEALS IN OUNCES
CHART 5

small amount of milk taken, as shown by test feeds, up to the seventh week. During that week the mother was persuaded to limit the feeds to six in twenty-four hours and in a fortnight to five feeds, the child became quiet and contented, and you will note the immediate improvement in the weight curve and in the quantity of milk taken at a meal.

Failures at the Third Week

Why is it that so many failures occur early, say at about the third week? Constantly I am being told, "The milk went

when I got up." The figures I have quoted point to one important cause, but there must be others. The woman—at any rate the working woman—gets up on the tenth day and resumes almost full household responsibilities and anxieties. This in itself is quite sufficient to diminish secretion. With her influx of work and worry there is increased loss of heat, because hitherto she has been lying warm in bed. All this means a largely increased need for food, does she get it? Are we sure that she has had sufficient rest after the mental and physical strain of her confinement? If we could keep the working-class women a few days longer in bed (and in this respect the provision of "home helps" might be useful) might we not be doing something towards the prolongation of breast-feeding? Another point at or about the tenth day, as has been pointed out to me, there is often a slight loss of blood from the uterus, we know that if a menstrual flow occurs during lactation the milk is often altered in quality and diminished in quantity. Is it not possible, therefore, that if this slight loss occurs at or about the tenth day there may be such an interference with the milk production as to add one more factor to those already mentioned?

Then, too, the baby is undergoing new experiences, he is being introduced to a larger world, his mentality is disturbed possibly he is now in a cot instead of lying warmly in bed beside his mother. Is he kept as warm as he was? Are all this the effect of too hourly feeds, and quite possibly of too frequent night feeding (for it is surprising how often in investigating a case of indigestion we find by close questioning that even babies fed quite properly in the day are fed too often at night), and we arrive at a sum which may account, in many instances, for the failure which undoubtedly does occur at about the end of the first fortnight—in many instances, but not in all, for I have met with more than a few cases in which careful inquiry on the lines I have suggested has failed to account for the failure. Is it a failure common to all grades of society, and, if so, is it a stage in a greater affliction, the inability to suckle at all? Are there any women so constituted? Budin states that there are, and gives an example in his book *The Nursing*. I have never, in my private practice, met with such a case in a woman with normal breasts and nipples, but in my work as medical officer to infant welfare centres I have come across so many women who have solemnly assured me that they have never been able to suckle a child from the first day onwards that I am constrained to believe that there may be a very few cases of this type, in many of these, however, it might be found that the suction of an older and more robust child would be a solution even of this difficulty, and it is significant to note that in the

case described by Budin he states that the nipples were "unhiliated," a physical condition rendering it almost impossible to apply efficiently the necessary suction stimulus.

THE RELATION BETWEEN TRAUMA AND TUBERCULOSIS

FROM THE PHYSICIAN'S POINT OF VIEW.

BY

NORMAN TATTERSALL, M.D. Lond.,
Chief Clinical Tuberculosis Officer, Leeds

IN discussing the relationship of trauma and tuberculosis from the point of view of the physician I intend to confine my remarks almost exclusively to pulmonary tuberculosis, but there are two other types of tuberculosis associated with injury which may first be briefly mentioned.

1 *Inoculation tuberculosis*.—This is probably the only true form of traumatic tuberculosis, and includes such conditions as butchers' and pathologists' warts, also those cases in which a tuberculous condition follows a cut by a broken sputum flask or other infected agent. Such cases are uncommon, but at one time examples of traumatic tuberculosis, as they involve injury to the skin and the introduction of the tubercle bacillus from without. Their pathogenesis is so straightforward that they should not lead to any difficulty from the accident insurance standpoint.

2 *Acute military tuberculosis*.—This may occur as an immediate sequel to such injuries as a blow on a tuberculous testis, forcible movement of an old tuberculous joint, or operative measures on tuberculous glands, etc. In such cases it is obvious that the trauma has caused rupture into the blood stream of a tuberculous focus, and in spite of the necessary presence of the tubercle bacillus in such a lesion the trauma is still the essentially responsible factor in the ensuing train of events.

Passing to the relationship between pulmonary tuberculosis and traumatism, the first question which arises is the frequency of such occurrence. I have recently surveyed the histories of 300 consecutive cases of definitely diagnosed pulmonary tuberculosis, and find that whilst injury was suggested as a cause in six cases, there were four in which the evidence clearly linked up the onset of symptoms and the fact of injury. Small though this figure may appear, considerable sums of money may be involved owing to the liability of employers under the Compensation Acts, and it is important, therefore, that we should hold definite opinions as to the part played by trauma in such cases.

Dr Parkes Weber, writing on this subject in 1910, grouped the cases into

- Those cases in which no tuberculosis was known or suspected to exist prior to the injury.
- Those cases in which tuberculosis was known to be present before the injury.

This grouping may conveniently be followed, and may be compared with the classification of "duo to" and

* Read in opening a discussion in the Section of Tuberculosis of the Annual Meeting of the British Medical Association Cardiff 1928.

"aggravated by" service which are so familiar in the phraseology of the Ministry of Pensions.

The two following are examples recently under my notice, of injury to presumably healthy persons.

1. A finely built man, aged 42, with an excellent health record, received a severe blow in the left axilla from the mudguard of a motor car. He returned to work in three days but a fortnight later had cough and persistent pain in the side. Four weeks after the accident he left work feeling weak and ill. I saw him the following week and found hardly any signs except fine crepitations in the axilla. A radiogram showed a mottled fan-shaped opacity extending from the root to the periphery. The sputum was positive, and after an acute course he died in six months. There was no haemoptysis at the time of the accident or later.

2. An ex-sergeant aged 36 playing Rugby football regularly and in full training, during a game in December 1926 was heavily tackled another player falling with his knee on the back of the patient's right shoulder. After temporary attention he finished the game but the same evening had slight haemoptysis. He had slight cough and sputum for the rest of the winter and never felt fit enough to play football again. The cough disappeared in the summer but returned in September 1927. Finding his wind was poor he did not resume football last winter. In January 1928 (thirteen months after the injury), he had severe haemoptysis and I saw him for the first time. There were marked signs in the right lung, slight on the left and a positive sputum. He is still in a sanatorium, doing very well, the disease being of a chronic fibrotic type.

Note the very acute course of the first case and the slow development of the second. In each case symptoms started very soon after an injury and formed a continuous chain of evidence up to the time of diagnosis.

The question to be answered is whether the accident has (1) *localized* a tuberculous lesion at the site of injury, or (2) *mobilized* and activated an old tuberculous focus.

It has frequently been stated that injury produces in the tissues a state of lowered resistance on which is implanted a tuberculous infection, the tubercle bacilli being carried by the blood or lymph stream from some distant and possibly quiescent focus. There is, however, very little evidence that this ever occurs. Animal experiments on this point have only in rare instances produced positive results, nor does clinical evidence support this theory, as is instanced by the fact that accidental or operation wounds in tuberculous subjects heal quite readily.

Recent work by Opie and others shows that tubercle bacilli can be isolated from lung tissue or glands which show no naked-eye evidence of tuberculosis. If apparently healthy tissues so frequently harbour tubercle bacilli this theory of diminished local resistance can hardly be supported, as otherwise local traumatic tuberculosis would be much more frequent than is actually the case. It would appear, therefore, that in cases such as those quoted the injury has directly or indirectly affected an existing focus of disease. Probably in the acute case a caseous root gland ruptured directly into a bronchus and in the latter a latent apical focus was compromised or torn, disseminating the previously localized infection and leading to slow progression of a previously dormant lesion.

If this be true the difference between injury to the presumed healthy and the known tuberculous subject largely disappears and becomes one of degree only. Further, we know that *post-mortem* statistics yield evidence of latent or healed tuberculosis in 33 to 97 per cent of cases, and this might well become 100 per cent if recourse were made to animal inoculation. One German writer laconically observes "after all, everyone is a little tuberculous."

When injury affects the known tuberculous subject our knowledge is more exact. Rest is still the bed rock of treatment, and evidence of aggravation by undue exertion is frequent. Tuberculous disease produces physical changes in the chest which favour the transmission of external impulses to the affected area. Injuries—especially those involving compression, and which normally are resisted by the elasticity of the chest wall and contents—will be focused and will exert their greatest influence at that spot where adhesions or loss of elasticity of lung interfere with the normal mechanism of safety.

A point of some importance is that the *post-mortem* findings prove that after severe injuries the lung opposite to the side receiving the impact may show extensive damage to and even tearing of, healthy lung. Thus an impulse applied to one side may readily aggravate disease in the

other lung especially when adhesions, etc., favour the concentration of the stimulus at the affected spot. It is obvious therefore, that injury to the chest of a tuberculous subject may readily result in active manifestations of any form of pleural or pulmonary tuberculosis.

Nature of Injury

Most of the recorded cases of traumatic pulmonary tuberculosis have followed injuries involving compression, such as crushing by falls of coal, etc., or the impact of a large object against a considerable area of chest wall.

The infrequency of pulmonary tuberculosis after war wounds has been recorded by many observers. This may in part be due to the subjects being picked healthy men, but the fact that the passage of a high-velocity bullet through the chest will not produce the diffuse impulse of a crush may be an important factor. The intensity of the injury is probably less significant than its nature, especially as regards the element of pressure.

Injury to distant parts of the body may, through sepsis, etc., so debilitate a patient as to favour the lighting up of a previously latent lesion.

Clinical Aspects

The course of disease subsequent to injury may be acute, subacute or chronic.

Haemoptysis and pleurisy are symptoms of great importance, though neither is essential in establishing a claim for compensation. Their importance lies in the fact that they will assist in fixing a date of onset of symptoms, will usually lead to the seeking of medical advice, and haemoptysis in particular, will not only impress the patient, but, if observed by others, may be valuable corroborative evidence.

In every case most careful history taking is essential, as in the absence of dramatic symptoms the establishment of a claim to compensation may rest entirely on slight but persistent evidence of ill health which bridged the interval between injury and diagnosis. Bridge symptoms of this kind were well shown in the case of the footballer already quoted.

X-ray evidence may be valuable in demonstrating an old and possibly calcified lesion with evidence of recent acute spread. In several acute cases I have observed a fan-shaped area extending outwards from the root, suggesting the rupture of a caseous lung or root-gland focus into a bronchus, with acute bronchio-pneumonic spread.

How shall we assess the particular part played by injury in cases of traumatic tuberculosis?

In most cases it cannot be proved that, apart from the injury the patient would later on have suffered from tuberculosis, but if the evidence convinces us that trauma adversely affected the existing condition, it must be considered the materially effective cause of the present ill health.

The German accident insurance law allows a patient two years' grace in which to assert his claims and for "aggravation" of lung tuberculosis, six months, which may be increased in special circumstances. This appears to be a reasonable allowance.

The fact that the patient was "fit to work until the accident" may be claimed as proof of his perfect health, this is a fallacy which is daily disproved in the experience of most of us.

The consideration of the following questions in every case is suggested as an aid to arriving at a decision.

1. Was the patient actively or passively tuberculous before the accident, and if the former, what was his expectation of life?

2. Is the fact of injury definitely established, and was it of such a nature as to be likely to damage an active or quiescent lung focus?

3. What period of time elapsed between the injury and the diagnosis, and was this period covered by "bridge" symptoms?

4. Is the present condition of the patient and the course of the disease such as might be expected if the injury had reawakened or aggravated an existing latent or active focus of disease?

THE RELATION BETWEEN TRAUMA AND TUBERCULOSIS

FROM THE POINT OF VIEW OF ACCIDENT
INSURANCE *

BY

OTTO MAY, M D CAMB,

Medical Officer to the Prudential Assurance Company

I ASSUME that the opener of this discussion will have dealt with what I may call the theoretical aspects of the subject, so I propose to limit my remarks to its practical points in connexion with the Workmen's Compensation Acts. It is, I think, obvious that in the large majority of the cases in which tuberculosis has been said to supervene upon an injury the relation, if any, must be an indirect one, not one of direct infection by tuberculous material, such as is said to occur in the case of butchers' warts and allied conditions. By indirect I mean that there is no suggestion that the accident forming the basis of the claim resulted in the introduction of tubercle bacilli into the body of the workman, the assumption is that in some way the trauma activated some focus of tuberculous infection, the existence of which it is now customary to postulate in the majority of the population.

The possible cases of "traumatic tuberculosis" that may arise in this indirect manner may be classified into the following groups

A Those in which there is a history of previous clinical tuberculosis in the worker. These may be subdivided into

(1) Cases of alleged recrudescence of the disease at its original site, as a result of injury at that site

(2) Cases in which the injury is said to have generalized the original disease (quiescent or otherwise), resulting in military tuberculosis

B Those without a previous history of clinical tuberculosis. These may be subdivided into

(3) Cases in which tuberculous disease ensues at the site of an injury

(4) Cases in which pulmonary (or military) tuberculosis arises after an injury in some part other than the chest

Before dealing further with these four groups I think it well to emphasize the legal aspect as to the points on which it is necessary for an applicant under the Workmen's Compensation Acts to satisfy the court in order to obtain an award. He has to show that there is some incapacity—partial or complete—for work, and that this incapacity has followed an accident (or disease) arising out of and in the course of his employment. But it is not necessary for him to show that his incapacity is *entirely* due to the accident, it is sufficient for him to establish that the injury is a link in the chain leading up to his incapacity, even though it is only the last link in a long chain of causal factors. From this point of view liability under the Workmen's Compensation Act is entirely different from that under the ordinary accident insurance policy, in which the company accepts liability only when the incapacity is due "solely and directly to violence occasioned accidentally by external and visible means." From this aspect it is doubtful whether any cases of "indirect" tuberculosis would constitute a tenable claim under an accident policy, since it is difficult to imagine such a condition as having arisen "solely and directly" from an accident as defined

1 Recrudescence of a Pre-existing Focal Tuberculous Lesion

In my experience claims of this type are not so common as might be expected. Unfortunately I have no records of the cases that have come under my notice, and the following is the only one of this group that I can recall.

A female domestic had suffered from a tuberculous hip in early childhood which had healed after operative treatment leaving an ankylosed hip with some shortening. In the course of her work she slipped and fell on the injured hip. It was not a particularly severe fall, and did not incapacitate her at the time. A week or two later the hip which had given no trouble for several years began to be painful and the trouble gradually increased.

Read in a discussion in the Section of Tuberculosis at the Annual Meeting of the British Medical Association Cardiff 1928

until she had to give up work, and was found to be suffering from active tuberculosis with a breakdown of the old sinus, necessitating further operative treatment.

Needless to say, this case caused no difficulty from the medico-legal standpoint, it was a clear case for liability under the Act. One can, of course, imagine a case on these lines in which a longer interval occurs between the accident and the recurrence of the disease, in such an event it might well be argued that the recurrence was not the result of the trauma. I will return to the importance of the "time factor" in my comments on Group 3.

2 Military Tuberculosis Following Trauma at the Site of a Tuberculous Focus of Disease

In 1910 Dr F. Parkes Weber read to the Life Assurance Medical Officers' Association an excellent paper dealing with traumatic tuberculosis. In it he quoted a striking example of this group of cases.

A man aged 33 received a blow on the left testicle, followed by local and general symptoms. Eight days later he had a rigor and seventeen days after this he died of military tuberculosis. Necropsy showed that the left epididymis contained a softened caseous nodule smaller than a small cherry. Both lungs were full of military tubercles but no other tubercles were found except a few in the renal cortex.

There seems little room for doubt that the blow on the testicle led to the dissemination of the infection from the old caseous focus at that site. A good many similar cases have been recorded in surgical literature—of military tuberculosis as a sequel to operations on tuberculous bone or glands, or the forcible manipulation of a tuberculous joint. In a case of this type the relation of the trauma to the fatal issue is so clear that it will present no difficulty should the question of the liability of an employer under the Workmen's Compensation Act arise.

3 Cases of Tuberculosis Arising at the Site of an Injury, without History of Previous Tuberculous Disease

Cases of this nature are common, and frequently constitute a difficult problem for the conscientious practitioner who is called upon to offer an opinion as to the relation between the injury and the ensuing disease. A typical example of this sort of case would be as follows. A worker, in the course of his work, slips and twists the knee, with the result that it swells, a synovial effusion is diagnosed, and the worker lies up for a time, while the effusion is gradually absorbed. In due course he returns to his job, apparently well. But either at once, or weeks or months later, the joint gradually becomes painful, and ultimately is diagnosed as tuberculous. In such a case a claim is frequently entered against the employer for the resulting disability, and the medical man is called upon for an opinion as to how far, if at all, the accident is a causal factor. It is, I think, obvious that there is little scope in a case of this sort for a dogmatic "Yes" or "No", the opinion must be reached by a consideration of the probabilities for and against a causal relation. On the one hand there is the undoubted fact that many, if not most, cases of tuberculous arthritis develop without any history of trauma. On the other hand, there is a considerable *a priori* plausibility in the argument that trauma, by injuring the tissues, renders them more liable to become the seat of infection, and it is, in fact, the current teaching in most textbooks of surgery that slight injuries do predispose to tuberculous arthritis. It is, indeed, hardly a matter for surprise that the medical evidence in these cases is apt to prove puzzling to the county court judge, especially if he should be sitting without the help of a medical referee.

Is there any working rule that the harassed practitioner may take for his guidance in such a case of "traumatic tuberculous arthritis"? I can only define my own line of procedure when called upon to decide whether a particular patient should be encouraged to enter a claim. I refrain from dogmatizing, but state in my report that it must remain a question of probabilities, if there is a history of the injured part never having quite recovered, but of having gradually drifted into a state of disease, then I am willing to testify as strongly as possible in favour of the workman. If, on the other hand, there is a history of a clear interval of apparently full recovery between the

injury and the onset of disease, I always take the line that the doubt is too great to permit me to uphold a causal connexion between the two conditions. One may, of course, be doing an injustice to the workman in taking this attitude, but if, as I read the law, the onus is on him to establish his case—that is, to convince the court that the balance of probability is definitely in favour of his plea—I cannot see on what grounds one can support his claim except to agree as to the possibility of its being correct. I willingly admit that there is little logic, and less science, in this arbitrary rule, but, provided it does not assume the pose of pontifical infallibility, a touch of dogma is of more practical help in the dispensation of justice than the cleverest exposition of scientific agnosticism.

4 Cases in which Pulmonary Tuberculosis Arises after an Injury to Some Other Part of the Body

These are perhaps the most difficult cases of all in which to try and hold evenly the scales of justice between the workman and the employer. In none is there greater need to bear in mind the fallacy of *post hoc, ergo propter hoc*. The Pensions Boards have had, as is well known, a difficult task in dealing with the large numbers of cases of pulmonary tuberculosis alleged to be caused, or aggravated, by military service. The problem is similar in workmen's compensation claims. How far, if at all, is the development of pulmonary tuberculosis in an injured workman attributable to the effects of the precedent accident? The comments made above under Group 3 apply, in principle, here. If the injury is one which produces "constitutional disturbances" to a severe degree, leading to severe debility, and the pulmonary tuberculosis gradually supervenes without any return to normal health, then I think that the balance of probabilities is strongly in favour of the injury having been a causal factor in the development of the disease. The following case may be cited as an example.

The workman was a lad of 18 of good personal history, employed as an electrician's mate.

Family History.—Father, mother, and sister were strong and healthy. One brother developed palsy in June 1924, he was sent to a sanatorium for six months and made a good recovery. No relative had ever had consumption.

On March 17th 1923, while working at an electric light fitting in a meat-shop he fell being unpaired on a meat hook which penetrated deeply into his left buttock. This caused profuse bleeding and he was taken to St Bartholomew's Hospital where he was an inpatient till June 21st 1923. The wound became septic necessitating irrigation by the Carrel Dakin method. An x-ray photograph on May 10th showed considerable bony destruction of tuber ischi. Up to this time the boy was seriously ill with high fever.

On May 15th sequestrectomy was performed. After this the cavity gradually healed the temperature settled to normal and he was sent to a convalescent home on June 21st.

He returned to work on August 13th but had to give up after fourteen days as the wound broke down superficially.

On October 8th he started work again and remained at work till May 1924, when he had to give up as he felt too ill to continue. During all this period he felt weak and seemed to get thin and in the latter part he fainted twice when at work.

In June 1924 he was certified by his panel doctor to be suffering from early pulmonary tuberculosis and in July he was admitted to the King George V Sanatorium. His condition became worse and he was discharged—taken home by ambulance—on November 7th 1924.

He died of pulmonary tuberculosis and tuberculous enteritis on August 11th 1925. There was no post mortem examination.

In this case I felt justified in giving the opinion that the prolonged septic illness resulting from the accident was at least a contributory factor in the evolution of the phthisis. Proceedings were accordingly taken against the employer, and, after the usual "conflict of medical evidence," judgement was given in favour of the applicant (who died two or three weeks after the hearing).

In contrast to the above, I should like to summarize another case, in which I was not directly concerned. It was that of a man who, in the course of his work, received a small piece of metal in his eye. It set up a traumatic cataract in the eye, which kept the man from work for over a year. As a result he had a good deal of mental worry, and perhaps some actual privation from reduction of income. Two years later he was diagnosed as suffering from phthisis. In this case also it was adjudged that the injury to the eye played an effective part in the develop-

ment of the phthisis, and he was awarded compensation under the Act. Personally I disagree with this decision. I do not think that one could go further than to admit the possibility of it having played such a part to assume, as the judgement implied, that there was a strong probability that, without the accident, the man would not have developed phthisis, seems to me unjustifiable and to be a loading of the scales against the employer to an unwarrantable extent.

In conclusion, I would again emphasize that the whole problem for the medical practitioner confronted with the duty of giving an opinion on the relation of trauma to ensuing tuberculosis is in his estimating the probabilities of a causal relation. If he is satisfied, from a review of the whole case, that the balance is definitely in favour of the view that without the trauma, the ensuing tuberculous disease would not have developed when it did, then, and only then is he justified in supporting a claim under the Workmen's Compensation Act. If, on the other hand, he comes to the conclusion that the causal relation, while possible, is not definitely probable, then he should say so, and refuse to support the claim.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

AN UNUSUAL CASE OF OBSTRUCTION OF THE SMALL INTESTINE

The following case, in view of the rarity of the condition, appears to be worth recording.

A carrier aged 36 was admitted to a medical ward of the Royal Alexandra Infirmary, Paisley under Dr William Clow with the complaint of periodical attacks of abdominal pain of two years' duration. The pain began to the left of the umbilicus and appeared to pass to the right side somewhat lower down. This pain was not associated with the taking of food but on two occasions about the time of his admission to hospital it was relieved by vomiting. Latterly on two or three occasions visible peristalsis was seen to begin in the left hypochondriac region and to travel in a ladder-like pattern to the right iliac region. The bowels were regular there was no distension or rigidity, but some deep tenderness was present to the left of the umbilicus. The patient had a small epigastric hernia and pressure on this with reduction seemed to give ease and on one occasion completely abolished peristalsis. For this reason the hernia was cured by a minor operation but this gave no relief to his symptoms. A barium meal followed by an x-ray examination did not reveal anything abnormal. An exploratory operation was now performed and a tight annular stricture was found on the small intestine towards the lower end of the jejunum. Higher up there was a band probably the result of old tuberculosis of the mesenteric glands and this was divided. The area bearing the stricture and two nodules in the mesentery were excised and an end-to-end anastomosis was done. The patient's recovery was uneventful.

Dr Mary Burd Hannay, pathologist to the hospital, reported on the specimen as follows:

The specimen after fixation measures about 3½ inches in length. There is a constriction 1½ inches from the wider end. The lumen at the cut surface of the narrower end of the bowel is ¼ inches in diameter and at the wider end 2 inches. The constricted area shows some puckering and measures about 1 inch in transverse diameter and about 1/8 inch in longitudinal section. There is an acute angle at the constriction on the anti-mesenteric border. Opened along the mesenteric border the specimen shows a slightly irregular ulcer completely surrounding the bowel opposite the constriction and measuring 1/2 to 3/4 inch in width. The lumen towards the narrow end of the bowel would admit a large probe that towards the wider end would admit the little finger. At the constriction the bowel wall is 1/4 to 3/8 inch thick. The muscular coat of the wider piece of bowel is 1/8 inch thick and that of the narrower 1/16 inch.

Microscopically a section through the constriction shows an irregular glandular growth on the mucous surface infiltrating the muscle and almost reaching the peritoneum. It has the characters of a glandular carcinoma. One of the nodules from the mesentery is a lymphatic gland and shows secondary tumour growth both inside the gland and outside the capsule. The other nodule is new growth but is apparently not in a lymphatic gland.

The pathological condition in the small bowel appeared to be the primary focus, and no other areas were found to be diseased.

Paisley

TREATMENT OF PAPILOEDEMA WITH INCREASED INTRACRANIAL TENSION,

THE two cases here recorded may be of interest in connexion with Dr C O Hawthorne's article on recovery from symptoms of intracranial tumour, which was published in the *British Medical Journal* of October 20th (p 689). They illustrate particularly two points (1) that, though more than one feature suggests cerebral syphilis, the Wassermann reaction in the cerebro-spinal fluid of both was negative, (2) that early decompression may save the patient's vision. They further suggest that, since complete resolution of papilloedema does happen spontaneously, it is much more likely to occur if embarrassment of the cerebral circulation is relieved by trephining.

CASE I

An unmarried seamstress, aged 28, complained on November 7th, 1927, that for two or three weeks she had had misty vision and difficulty with her work. She had severe headache during one week, and vomited twice during that time without obvious cause. On examination the vision in the right eye was found to be 6/18, improved to 6/10 by a +1 sphere. The vision of the left eye was 6/18, unimproved by correction. There was concentric contraction of both fields and a central scotoma for red and green in both eyes. Marked papilloedema was present, the swelling being +3 dioptres for the right eye and +5 for the left. The cerebro-spinal fluid obtained by lumbar puncture was clear, but under considerable tension. The Wassermann reaction was negative, and there was no evidence of neuro-syphilis. The family and personal histories were negative, except that six years previously her sister had proptosis of the right eye with diplopia, this was remedied by mercury and iodide treatment.

The present patient was given mercury and iodides internally and injections of mercury. She rapidly improved, and on November 22nd 1927 the vision in both eyes was 6/10, there was no scotoma for red and green and the peripheral scotoma had diminished. The patient stopped her treatment—contrary to instructions—and did not report for two months. She then returned and it was found that the vision in both eyes was 6/24 and that the papilloedema and scotoma had returned. She was admitted to hospital as an inpatient, no definite diagnosis was made, and she was finally discharged relieved of all symptoms apart from optic atrophy. At the present date—a year after the onset—she is apparently quite well but the vision in the right eye is 6/36, and in the left eye only perception of light. She has been given mercury and iodides continually.

In this case the diagnosis is uncertain, but a syphilitic cause is suggested by the therapeutic test and the family history. Had she been trephined in the early stage she would probably have retained her vision.

CASE II

The second patient was a married quarryman, aged 55, who had had six children. There had been no miscarriages and there was no personal or family history of syphilis. At the beginning of last July he was struck on the head by a falling rock, no injury beyond a superficial scalp wound was detected at the time. A week later distressing headaches started and continued with increasing severity for three weeks for the last ten days of this period there was frequent vomiting.

When examined a month after the injury I found him drowsy, he yawned frequently, was difficult to rouse and his speech was slurred. The pulse was 50, the pupils were equal and reacted to light. Both knee-jerks were increased and the Babinski reflex was extensor on both sides. The left fundus showed a definite early papilloedema, with haemorrhage. In the right eye the edges of the disc were obscured and the veins were distended. The Wassermann reaction of the blood was positive, the cerebro-spinal fluid was not under tension and showed no evidence of neuro-syphilis.

Until August 11th the condition steadily advanced with increase in the papilloedema, vomiting was pronounced and rendered feeding impossible. Decompression became an urgent necessity. The only localizing signs were papilloedema more marked on the left side, the Babinski reaction more pronounced on the right, and the headache was worse in the left fronto-parietal region, about the site of the injury. Subtemporal decompression revealed intensely congested brain, pulsation was not perceptible, the dura was not thickened and no induration was felt on probing. Two months later there was no trace of papilloedema, restoration of sight was complete and he was quite well except for slight slurring of speech and somewhat lowered mentality. The abdominal and cremasteric reflexes were not obtained, other reflexes were normal. There was a small hernia cerebri which had not increased in size since the operation. He was able to go about, but felt too weak to recommence work.

Here again the diagnosis is uncertain and the complete absence of changes in the cerebro-spinal fluid is noteworthy. The facts that the serum Wassermann reaction was positive on two occasions and also that the patient improved after decompression combined with the administration of mercury and iodide suggest the existence of vascular cerebral syphilis, which his general appearance supports. In any

case the decompression, which was performed to save his life, has also preserved his sight.

D O M S,
Honorary Ophthalmic Surgeon, Carnarvon
and Anglesey Infirmary.

PERIOSTITIS OF TIBIA FOLLOWING AMOEBIC HEPATITIS

THE following notes of a case of amoebic infection of the liver seem to merit publication for several reasons. In the first place the clinical evidence suggested a large degree of abscess formation in the liver, and this was supported by an x-ray examination and the leucocyte count, yet all the symptoms cleared up rapidly with emetine injections. Next, it is rare to find this condition present in women, so far as I am aware. Thirdly, a remarkably long period elapsed between the time when the patient left India and the onset of the symptoms. Lastly, an interesting point is that the infective periostitis of the tibia yielded pus exactly similar to that produced in amoebic abscess of the liver.

A woman, aged 46, had lived in India from 1896 to 1922. There was no history of dysentery or malaria, but in Bombay, in 1921, she had had inflammation of the liver, which was cured with emetine injections. Since leaving India in 1922, she had had persistently poor health though there were no definite signs but only occasional looseness of the stools and general abdominal discomfort. She had feverish attacks in April and May 1928 which were described as gastric influenza. The temperature was 103° for one week but then subsided.

In June 1928 she was complaining of chronic indigestion and was afraid to eat anything. There was general abdominal discomfort with pallor and emaciation and tenderness over the right hypochondrium. Some dullness was found at the base of the right lung with diminished vocal resonance and loss of breath sounds. The only other signs were intermittent pyrexia and rigors. A blood count showed a moderate polymorphonuclear leucocytosis with a haemoglobin percentage of 40. An x-ray examination on July 17th revealed that the diaphragm was raised up to the fourth rib by a rounded enlargement of the right lobe of the liver.

Starting on July 20th injections of 2 grains of emetine were given daily for twelve days. There followed a rapid fall in the temperature and subsidence of all the symptoms. The appetite returned and the indigestion vanished. On August 1st a redness appeared over the area of the left tibia suggesting at first erythema nodosum. The temperature at night rose to 100° the pain increased and fluctuation was present. An x-ray examination showed a diffuse periostitis. Incisions released very thick reddish brown pus which was sterile, no organisms were seen. Convalescence followed the ordinary surgical treatment which included the removal of small necrosed bony fragments along the middle two-thirds of the tibial shaft.

R HAMER HODGES, M B

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS

GUILDFORD DIVISION

Local and Regional Anaesthesia

At the annual meeting of the Guildford Division of the British Medical Association held on October 10th, Mr H S SOUTTAR delivered an address on the subject of local and general anaesthesia.

Local anaesthesia, said Mr Souttar, had until recently been somewhat neglected in English surgery. On the Continent it was the usual method of choice for operations of any description, and its application had become one of the most highly developed branches of surgical art. The greater attention paid to general anaesthesia in England and America and the high degree of skill developed by those who specialized in this work were no doubt responsible for this. But there could be no question that in local anaesthesia we had a very powerful method of great advantage to the patient, whether we used it alone or in combination with general anaesthesia, and there were few practitioners in any branch of surgery who would not find it of great utility in their work. By its means small operations could be carried out with facility and economy, and the general practitioner would find it one of his best allies. On the other hand, the use of local anaesthesia in major surgery enabled us to carry out with complete safety operations which under other methods involved grave risks.

In cranial surgery its introduction had revolutionized the whole of our technique, and by its means the heavy primary operative mortality of these operations could be almost abolished, whilst in extensive gastric operations its effects might be almost as striking. In these large operations the advantage of local anaesthesia was the abolition of shock, which resulted from the complete elimination of all afferent impulses. We were rather apt to forget that general anaesthesia, although it rendered the patient unconscious, only protected him in a variable degree from violent disturbances of those lower centres upon which in fact his life depended.

For operations of any magnitude, said Mr. Souttar, the combination of local with general anaesthesia was ideal. The equipment required was very simple, and consisted chiefly of a first-class syringe with fine needles of varying length. For most operations a 10 cm. Record syringe with needles up to 5 cm. in length would be sufficient, but for larger operations a powerful metal syringe capable of holding 50 c.c. and with convenient finger grips was essential, whilst needles as long as 12 cm. would be found a great convenience. The solution most generally useful was 1/2 per cent. novocain to which a few drops of adrenaline had been added immediately before use. It was essential that the solution should be absolutely fresh and sterile, and the most convenient method for its preparation was to pour boiling water on tablets of novocain and adrenaline: a stale solution was perfectly useless. Such a solution might be injected in very large quantities, and even 200 c.c. or 300 c.c. might be injected with impunity. Where a rapid action was required it might be used in a strength of 1 per cent. whilst for local application in the urethra a 4 per cent. solution would be required. Local anaesthesia might be produced by several distinct methods of which the most important were local application, local infiltration, and nerve blocking or regional anaesthesia. The first of these could only be used on mucous membranes and raw surfaces since none of the available drugs would penetrate the skin. It was thus restricted to the nose, the eye, and the urethra. The nose might be plugged with strips of gauze soaked in a 20 per cent. solution of cocaine, but if adrenaline were added a 5 per cent. solution would be found to be equally effective and much more economical whilst the haemostasis was superior. In the eye from 1 to 4 per cent. solutions might be used with a trace of adrenaline. In the urethra cocaine was on no account to be used since it was rapidly absorbed and severe toxic symptoms might be produced. A 4 per cent. solution of novocain would as a rule give all the anaesthesia that was necessary. Local infiltration was the method most generally useful and was all that was required for minor surgical procedures. The solution commonly used was 1/2 per cent. novocain to which a few drops of adrenaline had been added and practically any quantity required might be injected with perfect safety. The addition of the adrenaline was essential, since by constricting the vessels it not only prevented bleeding but limited the anaesthetic to the region required, increasing its local effect and preventing its rapid absorption into the circulation and the toxic symptoms which would necessarily result. In making the injection one of two methods was adopted—*injection into the dermis or into the deep tissues*. The former was essential along the line of incision, and should result in the raising of small swellings as the injection was made. Each swelling was itself anaesthetic and might be used as the starting-point for further injections. But if the deep tissues were to be entered these too, had to be infiltrated, and in an extensive operation it would be better to carry this out as the various structures were exposed. In this way any superficial tumour could be removed, and even very extensive procedures carried out with no shock and little or no haemorrhage. An important application of this method was in fractures and dislocations. Deep injections were made around the displaced ends of the bone, the tissues around both surfaces being thoroughly infiltrated. In a few minutes all pain would have ceased, the reflex spasm of the muscles would have disappeared, and the bones might be reduced to their normal relations with great ease. Regional anaesthesia was produced by the

blocking of a nerve with novocain, the injection being made either into the trunk or around it. In the latter case the solutions should be twice as strong, and only small nerves should be dealt with. For large trunks endoneurial injection was essential.

In most cases, said Mr. Souttar, the combination of local infiltration and regional anaesthesia would be found most satisfactory. As an example, he cited the resection of a rib for empyema. The solution was first injected along the line of incision over the rib, a row of little weals being raised as had been described. The needle was now inserted more deeply, and the tissues around the rib were themselves infiltrated with the solution of novocain and adrenaline. With a delay of ten minutes this might be all that was required, but if one wished to obtain perfect anaesthesia one had to block the intercostal nerves, reaching them either in the posterior end of the wound, or from the back at the point where they were lying just below the necks of the ribs. One per cent. novocain should be used, and the nerves both above and below the rib in question should be injected as well as the nerve belonging to the rib itself. In this was absolute anaesthesia, both of the rib and of the pleura, would be obtained and the operation could be carried out without any pain whatever. Regional anaesthesia could be applied to the fingers. A fine hypodermic needle was inserted at the base of the finger from behind, and 5 c.c. of 1 per cent. novocain was injected on each side, blocking the digital nerves. Five minutes later the finger would be found to be completely anaesthetic, and any operation required might be easily performed. The method might be used in the treatment of whitlow, provided that the injection could be made at a distance from the septic focus, although experience showed that there was less pain afterwards when these operations were carried out under gas. Any portion of the scalp might be readily anaesthetized by direct infiltration, or by simply surrounding it with a line of infiltration. Indeed, the whole scalp and cranium could be totally anaesthetized by a zone of infiltration encircling the head, since all the sensory nerves passed upwards in the subcutaneous tissues. By this simple method the suture of scalp wounds or the removal of small tumours might be greatly facilitated, whilst even the most extensive operations on the cranium and its contents could be carried out painlessly and with incomparable safety. The application of local anaesthesia to the teeth was now widely used. Apart from injection into the tooth sockets themselves, anaesthesia of the upper teeth was easily obtained by injections beneath the mucous membrane covering the outer surface of the superior maxilla, since the bone was there so thin that the anaesthetic readily penetrated to the dental nerves which traversed it. In the lower jaw the most perfect regional anaesthesia was obtained by injection of the inferior dental nerve, readily reached as it passed downwards on the inner aspect of the ascending ramus of the mandible. This method might even be used in the presence of sepsis, where local injections were on no account to be used lest they produced osteomyelitis of the jaw. For extensive chest operations, such as thoracoplasty, complete anaesthesia of the chest wall could be obtained by blocking each of the intercostal nerves where it was lying just beneath the neck of the rib. The skin of the back was first anaesthetized by infiltration in a vertical line over the transverse processes of the vertebrae, and through this anaesthetic area the needle was inserted just below each transverse process, and 5 c.c. of 1 per cent. novocain was injected at each point. By this method the patient was saved the annoyance of feeling repeated pricks, whilst complete anaesthesia of the whole of one side of the chest was rapidly obtained. As thoracoplasty was usually required in pulmonary conditions, such as tuberculosis, where a general anaesthetic was most undesirable, the regional method of anaesthesia was of peculiar value.

The abdomen, continued Mr. Souttar, had hitherto been almost monopolized by the general anaesthetist, but there were now methods at our disposal by which the most extensive abdominal operations could be carried out under local anaesthesia. For an operation on the stomach the skin of the middle line was first anaesthetized from the

osiform cartilage to the umbilicus, and, using the anaesthetized skin as a basis for operation, the rectus muscle on each side was freely infiltrated with 1/2 per cent novocain. The abdomen was now opened in the usual way, and the extraperitoneal tissues were infiltrated by injections made through the peritoneum from inside, ensuring absolute anaesthesia of that portion of the abdominal wall with which the surgeon came in contact. The liver was now drawn upwards, and the stomach downwards with extreme gentleness, and the left forefinger placed on the spine to the right of the aorta so as to push aside the v. cava. Guided by the finger, a long hypodermic needle was inserted into the retroperitoneal tissues on the front of the first lumbar vertebra, just below the liver, and 70 ccm of 1/2 per cent novocain were injected at this point. The result was a complete block of the splanchnic nerves. By this method excellent relaxation was obtained, and operations of the greatest magnitude could be carried out on the stomach and the upper intestine with entire absence of shock. Mr. SOUTTAR said he regarded this method of producing splanchnic block as one of the greatest of recent advances in the art of anaesthesia. The surgeon operated under ideal conditions, with a degree of relaxation unobtainable by ordinary methods, whilst the condition of the patient at the end of a long and difficult gastroectomy, such as might be required in the treatment of a jejunal ulcer, afforded very positive evidence of the elimination of shock. The only precaution required was to make sure by a slight withdrawal of the piston of the syringe that the needle had not entered one of the larger veins. In his experience the method had been devoid of complications, and he invariably used it in all operations on the upper abdomen, either alone or combined with a slight general anaesthesia.

The applications of local anaesthesia were limited only by the anatomical knowledge and ingenuity of the surgeon, for there was no operation which could not be carried out successfully by its means. The method, however, had to be carried out with extreme caution in the presence of sepsis, for it was obvious that the infiltration of septic tissues might assist the spread of the infection. A little ingenuity would often avoid this risk, which did not really detract from the great general value of the method.

Reports of Societies.

MENINGITIS

A WHOLE morning was occupied by the Section of Otolaryngology, Royal Society of Medicine, on December 7th, with a discussion on meningitis. Mr. SOMERVILLE HASTINGS presided.

Mr. G. J. JENKINS, in the opening speech, said that the principles which he had laid down as rapporteur on the subject at the International Otolaryngological Congress in Paris in 1922 had been verified by his further clinical experience. He had on that occasion explained the importance of distinguishing two groups of cases, in one the infection was primarily of a trabeculated part of the subarachnoid space, and in the other the infection was primarily of the cisterna pontis. In some cases of meningitis, even with micro-organisms present in the cerebro-spinal fluid, the patients had been known to recover with one or two lumbar punctures. This seemed to him to indicate, not that this procedure was a form of treatment, but rather that if the surgeon could help in some degree the cerebro-spinal fluid would overcome the inflammation, and without such help would fail. In many cases of meningitis the organisms had not reached the subarachnoid space, and the condition was due to infection in close relation to the outer surface of the dura—the *méningite de voisinage* of the French. Here the complete removal of the external inflammation would effect a good result. The difficulty was to know when the organism had not reached the space, and his impression was that it was only in very early cases that this procedure could be followed. Lumbar puncture should be regarded as a serious step, and not left to anyone to perform, it should only be employed for the purpose of

obtaining information as to the state of the meninges so as to help in deciding the line of treatment. The fluid should be removed very slowly, and not more than 6 ccm at a time, lumbar puncture should not be used for diagnostic purposes when septic meningitis was suspected. The changes in the cerebro-spinal fluid could be estimated only in relation with the clinical features. The clinical, and the cerebro-spinal fluid examinations would enable one to recognize very early and very advanced infections, but there was a wide doubtful group between these two extremes, and the speaker's inclination was to treat this group as probably infections of the subarachnoid space. He believed that if meticulous care were taken in cleansing after completing the external operation and before opening the subarachnoid, the risk from surgical intervention was much less than that of leaving things as they were. Dr. JENKINS proceeded to describe a method of washing out the subarachnoid space which had been used at King's College Hospital for many years in cases of septic meningitis which appeared to require drainage. He gave careful details of this intricate operation, which involved opening up the internal auditory meatus. It seemed to him that it followed the general principles of treatment of a septic focus, and was more likely to meet with success than simple drainage or lumbar puncture alone.

Mr. T. B. LAYTON offered some observations on otitic meningism—the name first applied by Dupré to a group of symptoms indicating meningitis, but showing normal fluid on lumbar puncture. Mr. Layton maintained that meningism did not occur with a local infection in anatomical relation with the meninges, or, if it did, that it must be considered as early meningitis. The only symptom of any importance to the ear surgeon was the rigidity of the neck, by the time there were symptoms connected with other reflexes a stage had been reached at which the chance of recovery was very small. Every case which showed rigidity of the neck, where there was any inflammation of the ear, should be called, not meningism, but meningitis, and lumbar puncture should not be performed, since such organisms as had got through the meninges would thus be sucked down from the ear to the region of the foramen magnum. He thought the better procedure was to open the mastoid, even though the local symptoms were only those of otitis media. The operation could be described as post-aural drainage rather than as an attempt to eradicate diseased bone. It might at times be a mistake to refrain from performing lumbar puncture, he described one case in which, after a mastoid operation on a child who had a rigid neck and an acute otitis media, miliary tuberculosis was found with a tuberculoma in the parietal region on the same side as the affected ear, but in general he thought there were good theoretical arguments against the use of lumbar puncture.

Mr. E. D. DAVIS dealt chiefly with the morbid anatomy of otitic meningitis, describing the paths of infection in such cases, the vulnerable points in the dura mater where it was pierced by nerves and vessels, and along the lines of sutures, also the methods of drainage considered from an anatomical point of view. He spoke of clinical types of infections of the ears which had produced meningitis. Persistent headache and pyrexia, and paralysis of the sixth nerve, afforded a serious warning of the spread of infection. Records of cases of meningitis which had followed chronic suppuration, reported by Logan Turner and others, showed that symptoms and signs of labyrinthitis were present in a large proportion. Such signs and symptoms, however, might occasionally be more or less absent, and changes in the cerebro-spinal fluid be the only indication. The fluid should always be examined when the slightest suspicion of an intracranial complication arose. He had never experienced any difficulty in connexion with lumbar puncture.

Mr. ERIC WILSON-WILLIAMS had been most impressed by the element of urgency in these cases of otitic meningitis. To do any good at all the diagnosis had to be made and the treatment started at once. It was not possible to await any elaborate investigation even a few hours would turn the scale. Moreover, in his experience such cases seemed to choose some such time as 1 a.m. on a Sunday to develop. Looking through his notes for the past three years he saw that he had operated in seven cases of

meningitis, and in one that he classified as meningeal reaction. His feeling was that lumbar puncture was of great assistance in deciding, not merely the diagnosis—for this might remain obscure even after lumbar puncture had been done—but the line of treatment. In these seven cases of definite meningitis he had had three recoveries and four deaths. The four fatal cases were not really germane to the present discussion, for they were not cases of otitis media so far as could be ascertained, three of them were pneumococcal meningitis and one was tuberculous meningitis. The three cases in which recovery followed were definitely otitic meningitis. One case which he had previously shown to the Section was that of a woman who was admitted to hospital with high temperature, neck rigidity, severe headache, and mental confusion. The cerebro-spinal fluid was quite turbid, not milky, but definitely more than opalescent, and was reported to contain many pus cells. There was a dead labyrinth. He performed a complete labyrinthectomy, and drained the meninges through the internal auditory meatus. After some improvement the cerebral symptoms returned, and he thereupon passed the curette down the internal auditory meatus, scraped out some debris, and re-established a drain of cerebro-spinal fluid; the woman got perfectly well. The cerebro-spinal fluid appeared to have some influence in limiting the spread of infection though not enough was known about it to enable one to say what made it better—as it probably was—than an artificial fluid. The protein content was possibly responsible for some bactericidal action. He did not himself see how the subarachnoid space would be disinfected by the introduction of disinfectants. He was always very sceptical about the value of disinfectants in contact with living tissues, because a disinfectant which was sufficiently powerful to kill off streptococci was likely to destroy the living cells long before the streptococci were affected. Perhaps in a late case which was not doing well he would employ the method of washing out, but he had had one or two successes with the drainage method, and in general he felt inclined to retain it. The urgency of the whole matter must dictate the procedure. When there was meningitis and any indication of aural trouble, it was necessary to open the ear and to decide on the findings at operation rather than to make the decision beforehand. In that way he thought a good many cases of meningitis would be treated early enough to avert a general infection.

Mr. HOLT DICKE raised the question whether the results of the treatment of meningitis were any better to-day than they were fifteen years ago, and if so, whether the improvement was due to earlier diagnosis. Patients were certainly received at a much earlier stage. The only two cases he had on record of recovery from meningitis when there were organisms in the cells had been treated by repeated lumbar puncture. He had tried all types of drainage of the basal cisternae with no results to his credit. Mr. Jenkins, in the method he had just described, washed from below upwards, that method might be supposed to diffuse the infection which originally was localized to one cisterna, and he had himself washed the other way—from the lateral ventricle to the lumbar puncture route—but even so he had had no recoveries. In spite of these more scientific methods were the results improved? To take an analogous example from the abdomen, where the method of washing out had had a vogue and had been given up, in an established case of diffuse peritonitis such hope as there was depended upon drainage at several points, was it not possible that in the ear better results might follow repeated lumbar puncture? He believed that the hope in the treatment of meningitis depended still on early diagnosis and repeated lumbar punctures, and that without a lumbar puncture there were no means of assessing the extent of the disease or deciding the line of treatment.

Dr. DAVID MCKENZIE described a case, supposed to have been meningitis, an operation was performed, but the condition proved to be encephalitic lethargia. In these cases it was necessary to make a lightning diagnosis, there was not time to await the microscopical examination of the cerebro-spinal fluid. As for the results of drainage, these were curiously varied. A line of successes might alternate

with a list of failures. With drainage the clinical picture was modified profoundly, the patient remained conscious until the end, but still suffered from pain and headache, and the speaker questioned whether his state was really bettered after drainage. Certainly surgeons by no means possessed in drainage a treatment on which they could rely for the cure of meningitis.

Mr. M. J. VLASTO thought that sufficient account was not taken of the type of labyrinthitis in connexion with meningitis. It was an important matter to distinguish the type of labyrinth with which one was dealing, and he thought that in a case in close relation to labyrinth infection he would be inclined to treat the focal cause as widely and efficiently as possible and let the labyrinth deal with itself.

Mr. JAMES HARRIS said that the question of operative intervention in meningitis had given him a good deal of anxiety. In many cases of meningitis one was conscious of the borderline, and was afraid to interfere with the meninges. This year he and his colleagues in Glasgow had had to deal with 14 cases of meningitis, of which 7 had recovered as a consequence of clearing out the local infection in the ear. In the 7 fatal cases he did not think any form of washing out or drainage would have had effect, 3 of the patients when admitted to hospital were unconscious. Lumbar puncture was always tried, and he had never found any great harm come from it. In the cases which eventually recovered no micro-organisms were found in the cerebro-spinal fluid, except in one in which the streptococcus was found on direct examination but could not be cultured. In all the fatal cases micro-organisms were found and cultured. He believed that there were two stages in the same type of meningitis, one recoverable, the other with the chances of recovery remote.

Mr. BROUGHTON BAILES had had only two recoveries in cases with definitely infected cerebro-spinal fluid. Both patients had also infection of the brain, and in one there was a cerebellar abscess. He confined himself to the brain condition, and both patients survived. It was necessary to be very much alive to any brain infection, and in the presence of such no washing out or drainage operation should be performed, but the brain only should be dealt with.

Mr. SIDNEY SCOTT said that it was quite clear from the discussion that the last word on this subject had not been spoken. The consensus of opinion seemed to be that the local infection should be dealt with first, and from this it might be inferred that a radical operation ought to be performed in all these cases. He mentioned a case in which the patient had all the signs of early meningitis, including rigid neck, intense headache, and fixed pupils, a lumbar puncture showed streptococci in the cerebro-spinal fluid. On opening the mastoid the cells were found absolutely normal. The mastoid was drained, but lumbar punctures were also repeated, and to this latter procedure he attributed the complete recovery of the patient. With regard to the labyrinth mentioned by Mr. Vlasto, under an anaesthetic one could determine whether a labyrinth was alive simply by spraying ethyl chloride.

Mr. MUSGRAVE WOODMAN thought there was a *via media* between the two distinct schools of opinion as to lumbar puncture, surely a lumbar puncture was of value in certain cases. There was all the difference between draining off a large quantity of fluid by lumbar puncture for the purpose of treatment and drawing off 1 c.c.m. for diagnostic purposes, the latter would obviate a false diagnosis in a case of encephalitis lethargica. Was there any serious objection to taking a very limited quantity for that specific object?

Mr. H. V. FORSTER said that the surgeon was continually confronted with the opposite dangers of doing too much and of doing too little. One difficulty was to determine when the labyrinth was dead, and Mr. Scott's suggestion was useful. He described one or two cases in his own practice, and a technique for dealing with brain abscess.

Sir J. DUNDAS GRAY referred to a Contuental treatment in which intravenous injections of antiseptic fluid were given, and Mr. E. WATSON-WILLIAMS said that he had tried this method in cases of suppurative labyrinthitis, injecting 1 c.c.m. of colloidal silver into the vein. The

injection was followed half an hour later by lumbar puncture, and the patient made a good recovery. Questions on detailed points in Mr Jenkins's technique for washing out the subarachnoid space were asked by Mr WATKYN THOMAS, Mr T B DOBSON, and the PRESIDENT, in reply to which Mr JENKINS gave some further information, and on the general principle added that, in view of the large number of cases of meningitis which terminated fatally, and for which nothing could be done, it seemed to him very undesirable that because with a minor procedure a few recoveries were obtained surgeons should rest there, and do nothing further. Ought not surgeons to try to improve their methods of treatment in dealing with these cases? The method he had described as followed at King's College Hospital was admittedly a dangerous procedure if not performed with meticulous care, but he held that it was in a line with surgical attack upon this disease.

Mr T B LAYTON, also in reply, said that the Section had been told of a number of cases which got well, although to all appearance they should have died. He himself had never been a "lucky surgeon," and such cases had never come his way. He had tried lumbar punctures, but he felt that in the early case better results followed the least intervention. Dr Dan McKenzie had laid down the proper principle when he said that the thing to do in treating these early cases was to deal with the local infection and to leave the meninges alone, not even a lumbar puncture should be performed. He had never yet had a case recover in which organisms were found in the cerebro spinal fluid, either on direct examination or subsequent culture by the bacteriologist. Mr E D D DAVIS expressed agreement with Mr Jenkins that something ought to be done in these cases. He himself always performed lumbar puncture, removing 5 c.c. in a test tube, lumbar puncture, in his experience, had never resulted in harm.

PRELIMINARY MEDICATION FOR ANAESTHESIA

At a meeting of the Anaesthetic Section of the Royal Society of Medicine, held on December 7th, Mr STANLEY ROWBOTHAM read a paper on preliminary medication in anaesthetics.

Mr Rowbotham stated that the subject had not generally received the attention that was its due, and acknowledged his debt to Gwathuoy as pioneer in this field. A nervous and apprehensive patient needed soothing, and for this purpose morphine alone was not sufficient. That such soothing might be possible was suggested by several facts. It occurred in cases of rectal ether anaesthesia, the more a patient reacted to preliminary medication the less anaesthetic he required at the time of operation, with lighter anaesthesia he passed more quickly out of the influence of the anaesthetic, but remained under the influence of the preliminary medication, thus suffering less after-pain and being unconscious of sickness and discomfort. He found paraldehyde, either alone or in combination with morphine, heroin, hyosine, chloroform, etc., to be specially effective. The paraldehyde was given per rectum with or without chloroform, the other drugs being given hypodermically. It had been found that a combination of drugs acted more powerfully and for longer periods than either drug alone. Preliminary narcotic drugs reinforced each other, but anaesthesia following was considerably reinforced. After such drugs had been given abdominal relaxation could be completed with nitrous oxide and oxygen or ethylene. Cocainization of the larynx made it possible to pass intratracheal tubes after the administration of nitrous oxide and oxygen. Ether became a very powerful anaesthetic, and chloroform might become positively dangerous. The depression of the blood pressure and respiration was comparable with that produced by morphine or heroin alone, and the author had never experienced trouble from an unusual fall of blood pressure. For the purposes of administration four groups of patients were recognized. In the first group were children under 7 and the sick and puny over that age, very old and feeble adults and those with low blood pressure, toxic and shocked patients and those anaemic from haemorrhage, and patients who had suffered from long-standing pyrexia. In the

second group were normal children over 7 and normal adults. In the third group were alcoholics and very nervous patients and athletes over 25. The fourth group comprised only patients suffering from Graves's disease. To patients of the first group paraldehyde, 1 drachm per stone of body weight, was given per rectum one hour before operation, and at the same time a hypodermic injection of atropine gr 1/200 to 1/100. The paraldehyde alone was sufficient to cause unconsciousness. To the second group paraldehyde was given in a similar manner, but reinforced by heroin gr 1/60 per stone of body weight, one and a half hours before operation. The third group was treated as the second, but in addition a further hypodermic injection of a quarter to half the original dose of heroin was given three-quarters of an hour before operation. Another method applicable to this group was to give paraldehyde as before, and, in addition to heroin or omnopon, etc., to inject hyosine hydrobromide gr 1/200 to 1/100 one and a quarter hours before operation. The hyosine produced sleep in most cases, but occasionally induced delirium, so that it was necessary to administer trial doses a day or two before operation to ascertain the patient's reaction. The cases in the fourth group were notoriously difficult to deal with. When the operation was carried out under local anaesthesia quiet and repose were essential. A trial dose of hyosine was required. Potassium bromide and chloral were given the night before the operation, and heroin or omnopon or morphine one and a half hours before operation in combination with hyosine, unless this had been found unsuitable, and a chloroform suppository was placed in the rectum. One and a quarter hours before operation paraldehyde in olive oil was given per rectum in the proportion of 1 drachm per stone of patient's weight to half an ounce of oil per drachm of paraldehyde. For very obese patients the full dosage might be reduced 20 per cent. If the patient was still awake three-quarters of an hour before operation one-half to two ounces of a mixture of ether and olive oil in equal parts might be added to the paraldehyde already in the rectum. In cases other than Graves's disease the paraldehyde was dissolved in saline in the proportion of 10 to 1. This solution has to be administered at blood heat. The colon was emptied by a soap enema the day before operation unless the bowel had been well emptied by aperients. A saline wash-out was given not less than three hours before operation, no attempt being made to cleanse the bowel thoroughly, as this would exhaust the patient. As a rule the patient anaesthetized by these methods was asleep in fifteen minutes, often in less. Sleep usually deepened, and in twenty to forty-five minutes the patient could not be roused. The conjunctival reflex was often lost, but the corneal remained. The muscles were flaccid, but sensibility to pain persisted. This was unfortunate, as sometimes great difficulty was experienced in administering a spinal anaesthetic, though local infiltration of the skin with novocain might obviate this difficulty. Unconsciousness persisted for variable times. The average case would sleep for twelve hours after nitrous oxide and oxygen, and remain drowsy for another eight hours or so after paraldehyde. After operation the paraldehyde might be left in the rectum, or it might be removed by a rectal tube, or a further dose of paraldehyde might be given as the patient returned to consciousness. A patient could be kept quiet for two and a half days by repeated doses. After-effects were slight, and consisted of headaches and confusion. Nausea and sickness were seldom met with. Toxic cases remained unconscious longer, and required smaller doses than the normal. The chief contraindications to the method were diseases of the bowel, such as piles, fissure, and operations on the lower bowel, and cases in which a spinal anaesthetic was to be given. In the latter cases the subsequent flaccidity of the muscles might cause the paraldehyde solution to be evacuated. The speaker stated in conclusion that, while the method was not perfect, it had served him in his practice. Possibly better results might be achieved with avertin, but for the time being this drug could not be tested, as supplies were unobtainable in this country.

Dr J. BLOMFIELD criticized the adoption of the method as a routine. He asked whether there was not danger of

inefficient ventilation of the lungs and so of lung congestion later? Was there not danger also of blood trickling down the throat? Dr I MACILL said he had had favourable experience of the method in selected cases. Admixture of paraldehyde with olive oil rendered the use of chloroform unnecessary. The disadvantages of the method were the necessity of a preliminary visit to the patient and the administration of a drug per rectum. Owing to the lowered blood pressure bleeding was less than under ether, especially in throat cases. The method was contraindicated in chest operations such as for thoracoplasty. Three of his cases had exhibited complications after the use of the method. In two there had been persistent vomiting on the following day, but both responded to calomel. Another case showed remarkable idiosyncrasy to a small dose. Dr I T LAVIS mentioned a case in which a child became maniacal after the use of the method.

Dr RAMSEY PHILLIPS described the case of an athlete in whom, despite the method, he had had the utmost difficulty in inducing anaesthesia although the patient was apparently asleep. At the third attempt anaesthesia resulted, but was followed by great difficulties when the operation commenced owing to the slowness of the heart beat. This was remedied by administration of small doses of carbon dioxide. The patient eventually recovered sufficiently for the operation to be completed. The doses of paraldehyde given were small. Dr Z MERVILL objected to leaving his own end of the patient and working at the other, moreover, paraldehyde was not safe. Before the war when paraldehyde was given intravenously for anaesthetic purposes two deaths occurred. There was a distinct danger of idiosyncrasy to paraldehyde, and once given per rectum it was irrecoverable. He objected to it in cases of tonsils and adenoids. Its chief object was to get the patient on the table without his being aware of it, but surely twilight sleep was equally efficacious. Was there not also a distinct danger of rectal complications following the administration of paraldehyde? Further objections were the tremendous amount of extra work thrown on the hospital staff and the difficulty of timing the complicated injections when a series of cases had to be operated upon. Dr C H HUGHES firmly believed that premedication was very important in a percentage of cases. Dr HUGH PHILLIPS agreed that the lengthy sleep following the method greatly perturbed the nursing staff. It was invaluable, however, for use in children, especially in orthopaedic cases where great pain followed operation. He had been able to use it successfully in a patient aged 14 months. He agreed that paraldehyde was very useful, but that it should be used only in selected cases. Dr H A RICHARDS said that the question was whether the patient's feelings should be considered of more importance than the patient's safety. The method could not be considered a safe one, and was not to be employed indiscriminately. Dr ASHLEY DALY drew attention to the danger of chest complications, especially following operations on the upper abdomen. The nursing difficulties were very real, for instance, the timing of injections in hospital practice. There was also, in private practice, the question of cost. The prolonged sleep might necessitate the employment of two special nurses for two or three days.

CONVULSIONS IN CHILDREN

A MEETING of the Manchester Medical Society was held in the Medical Library of the Manchester University on November 7th, with the president, Dr R W ALKSDEN, in the chair. Dr C PIGER LAROC read a paper on convulsions in children.

Dr Lapage defined the following three classes of such convulsions. In the first he placed those associated with acute infections, such as encephalitis, encephalitis lethargica, and meningitis, etc. He also included convulsions of mechanical origin, as, for example, following birth injury, or haemorrhage with hemiplegia or diplegia, or malformations such as porencephaly, microcephaly, or brain tumours, abscesses, injury, or whooping-cough with haemorrhage. The second class comprised convulsions of metabolic and toxic origin, where the nerve endowment might be normal or abnormal. Examples of this class were the convulsions

of rickets with peripheral irritation or additional metabolic upset, of tetany and spasmodophilia with calcium deficiency, of simple overfeeding, or such severe metabolic upsets as uraemia, hypoglycaemia, naphthylaxis, and the onset of acute illness, etc. The third class contained the convulsions due to epilepsy, whether idiopathic or accidental. Dr Lapage said that if convulsions were correctly classified under these headings the prognosis and treatment were very much simplified. The importance of the signs of spasmodophilia, especially Chvostek's sign, was great, because if they were present there was considerable hope that the cause was not one of the less tractable conditions, spasmodophilia being due to some alteration of metabolism which was usually amenable to treatment. Continued fits in children were often due to an attack of post-encephalitis which left an irritable area in the brain. As the result of increasing experience, he had come to believe that many cases, which would formerly have been put in the class "epilepsy," should really be classified as "organic convulsions caused by some brain lesion." Post-encephalitis was much more common than is usually supposed. Attacks of stimulating petit mal should be distinguished from petit mal, a condition in which the prognosis was quite good and in which there were very large numbers of small "absences," but never real fits. They must also be distinguished from attacks like petit mal which occurred in cerebral lesions, especially cerebral or cerebellar tumours. Precursors of Jacksonian epilepsy might appear as sudden momentary attacks which caused the child to fall down, either backwards or forwards. Cerebral surgery in these cases was often disappointing, but it must always be remembered that hydrocephalus of the brain even in young children was not unknown. The possibility of a syphilitic origin must also be remembered and a Wassermann test be performed. In the treatment of epilepsy, Dr Lapage emphasized the value of luminal, the need for careful supervision of the diet and the daily habits. He reported a case of successful control of fits by a ketonic diet.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY

A CLINICAL meeting of the Aberdeen Medico-Chirurgical Society was held in the Aberdeen Royal Infirmary on December 6th with Professor ALEXANDER LOW, the president, in the chair. Mr F K SMITH demonstrated by cystoscopy and under spinal anaesthesia a sessile tumour of the fundus of the bladder, and discussed the diagnosis and classification of tumours in this region. The most satisfactory line of treatment in the type of case demonstrated was excision of the tumour and the whole thickness of the bladder wall, with possibly the later implantation of radium. Mr Smith then showed two cases of Banti's disease which had been under observation for several years. In the first case splenectomy had not been performed, and in the second case the spleen, which had been removed eighteen months previously, showed the typical changes associated with Banti's disease. The patient had an interval of good health, but intestinal haemorrhage had recurred. The cases of Banti's disease were discussed by Dr A GREIG ANDERSON, who pointed out that there was no definite consensus of opinion upon the time relation between the onset of cirrhosis of the liver and spleen in this condition. Mr ANDREW FOWLER reported a case of diastasis of the lower end of the femur in a boy aged 12 years, the accident had happened four weeks before admission. There was distinct hollowing above the patella and a hard bony projection was easily felt behind and to the inner side of the hamstring tendons. There was very little effusion into the knee joint. The chief interest in the case was from the point of view of treatment. Should replacement of the epiphysis by manipulation be attempted? Was open operation advisable, and, if so, what method of approach would give the easiest access? Should the condition be left and osteotomy be performed at a later date? Mr ALEXANDER MITCHELL thought that an open operation was indicated, in his experience it had given excellent results. Dr GEORGE SWAPP demonstrated a case of malignant ulceration of the breast of long standing. Healing of the ulcer had occurred with x-ray therapy and the application of brilliant green. Metastatic nodules had, however, appeared in the subcutaneous tissues of the chest. Dr Swapp also reported a case of acute ileocolitis where caecostomy had been necessary on account of acute abdominal distension and paralytic ileus. Recovery had been satisfactory and was, in Dr Swapp's opinion, due to the administration of intravenous hypertonic saline with anti-gangrene serum.

Rebels.

SURGERY OF THE STOMACH

PROFESSOR HARTMANN is known to all as one of the most distinguished surgeons that France has produced. He is a general surgeon in the present day acceptance of that term—that is, he is essentially an abdominal specialist with some leanings towards urology. It is impossible not to be impressed by the judicial nature of his writings. He looks back now over a career not easily matched in distinction and length; he sifts his great material and comes logically to the inevitable conclusions.

In the present volumes, the sixth and seventh of his series of surgical monographs,¹ he calls in the aid of his assistants, as on previous occasions. It will be remembered for example, that Okmezen, in the third volume of these *Traité de Chirurgie Anatomique-clinique*, contributed his memorable work on the surgery of the colon, without, however, studying closely its lymphatic drainage. The omission was shortly afterwards made good, happily in this country, by Jamieson and Dobson, and the two papers have done much to direct the course which colonic surgery has taken since. In the present volumes Professor Hartmann's assistants again fill in gaps by contributing special studies. They have provided, for example, chapters on gastroscopy, on experimental pyloric stenosis, on valvulus of the stomach, on duodenal compression and occlusion, and on duodenal anomalies. Some of these sections are very good indeed and a joint paper on the chemistry of the stomach after operation is instructive.

Hartmann's own contributions are concerned chiefly with ulcer and cancer of the stomach and duodenum, with important chapters on perforation of simple ulcers and malignant growths, jejunal ulceration, the non-malignant growths of the stomach, and the results of various operations. It is because he has followed his cases so well that his work is so important. He is impressed by the sclerosing gastritis which spreads wide from the crater of the chronic gastric ulcer. He is one of those who believe that this is not a mere secondary defensive fibroblastic proliferation, but an essential part of the disease, which he would prefer to call "gastritis sclero-ulcéreuse." The disappearance of the muscle bundles is the outstanding histological feature, as is now widely recognized—an important fact in the solution of the problem of ulcer-cancer. As for the malignant ulcer, Hartmann thinks that it is uncommon and is generally an ulcer malignant from the outset and not a transmutation. He compares it with the rodent ulcer of the skin. Hartmann remarks that Parisian surgery seems to have accepted the "cancerisation de l'ulcère" as a process so natural as to be indisputable; his own figures are strongly against such a view. In an analysis of 201 ulcers of the lesser curvature he gives the results of the various surgical methods which he has employed. Of seventy gastro-enterostomy patients, two afterwards died of cancer. These two were aged 51 and 57 respectively, with a two-year history of dyspepsia. The one died fifteen months after gastro-enterostomy, the other five years later. Both of these cases he thinks were malignant from the start. Resection of the ulcer as a routine does not necessarily save the patient from death later if the ulcer is really malignant, for in forty-four gastrectomies the ulcer turned out to be malignant on section three times, and all these patients died later. For hour-glass stomach he has done a variety of operations, and remarks that these cases never become malignant. In thirty-three cases he resected the lesser curvature by his own method. He had, he admits, gradually come to assume that removal of the ulcer gave better life results than gastro-enterostomy, but looking over the cases now he finds that this was not really so. One of the surprises of his review of his cases has been this fact. Peptic ulcer of the jejunum he finds much more often in males of his six personal observations there were five men and one woman. This number is small perhaps all

of us are only just beginning to realize how much commoner this complication is than we have believed in the past.

Reading through the synopsis of the after-histories of Hartmann's gastro-enterostomies we may now and again find suggestive symptoms the correct interpretation of which is open to comment. These symptoms in many cases eventually subsided, and it seems to be fairly certain that secondary ulceration may finally be recovered from without the complications which at times overtake others. It is heartening to find that in a series of 100 gastrectomies for cancer of the stomach 30 per cent of the patients were alive three years and more after the operation. Seventeen were alive five years and more later, and seven ten years and more up to twenty-one years.

Such careful work as will be found in these volumes needs no special recommendation to the reader, for all who take their work seriously will turn to them naturally.

CUSHNY'S "PHARMACOLOGY"

We are glad to learn that the late Professor CUSHNY'S *Text Book of Pharmacology and Therapeutics*² is being continued, and we welcome the ninth edition that has been prepared by Professors JAMIESON and GUNN. The production of this textbook was one of the outstanding services rendered to medical science by the author. He devoted much time to the revision of its numerous editions, and maintained a standard of critical accuracy that was exceptional even amongst first-class textbooks. His book, therefore, was a standard work of quite exceptional authority, and it is fortunate that the task of maintaining this high standard has fallen into such competent hands.

The editors have divided the book into sections, and each has revised about half the book. As was natural when dealing with a work of such excellence, the editors have made as few changes as possible, and the general form and scope of the volume have not been altered. The materia medica has been revised throughout to bring it into line with the tenth edition of the *United States Pharmacopoeia*. The new volume also includes notices of all the more important new drugs that have been introduced since 1924. Examples of such new substances are hexylresorcinol, carbon tetrachloride, ethylene, parathyroid extract, sulpharsphonamine, and triparanide. The chapters on endocrines have been largely rewritten, various improvements in arrangement have been effected, and the volume has been increased in size by about forty pages.

We feel grateful to the editors for having made no drastic changes in the well known volume that was an expression of the personality of its author. This book was written in 1899, and for a quarter of a century it was revised by Professor Cushny. The appearance of this new edition, the work of other hands, lends a sad significance to the last lines of the preface to the previous edition.

And here I cease to write but will not cease
To wish you live in health and die in peace
And let our Physicke rules that friendly read
God grant that Physicke you may never need

HUMAN HEREDITY

The substance of the book entitled *Observations on Human Heredity*³ earned for its author the Sir Charles Hastings Prize of the British Medical Association in 1927. Dr J. S. MANSON spent his prize money in printing this book. To win such a prize is no mean feat for a busy general practitioner to make such use of a prize is to demonstrate that the recipient is more than merely able and industrious—he is endowed with the qualities of generosity and sympathetic helpfulness. The prize was well awarded.

The family histories recorded were personally investigated by the author, they afford evidence that the hereditary constitution may not only yield a morbid diathesis, but also determine the actual location of defect and derangement. The part played by organic inheritance in the incidence of

¹ *Text Book of Pharmacology and Therapeutics*. By Arthur R. Cushny, M.D., LL.D., F.R.S. Ninth edition thoroughly revised by G. W. Edmunds, M.D., and J. A. Gunn, M.D., Sc.D. London J. & A. Churchill, 1928. (6 x 9 1/2 pp. x + 735 figures. 2s. 6d.)
² *Observations on Human Heredity*. By J. S. Manson, M.D., D.P.H. Manch. London H. K. Lewis and Co. Ltd. 1928. (Demy 8vo pp. x + 84. 19 figures. 8 plates. 6s. net.)

³ *Traité de Chirurgie Anatomique-clinique*. Sixième et Septième Series. *Chirurgie de l'Estomac et du Duodénum* (par A. M. Jamieson). *Chirurgie de l'Estomac et du Duodénum* (par H. K. Gunn). in oplo-mis has been demonstrated by animal experiments, and there is much statistical data to suggest the occurrence of a familial incidence in man. Dr. Maunon records the history of a family in which a highly malignant sarcoma recurred in several generations, and always in the same situation. Other cases recorded include humeral cataract, spastic paraplegia with ataxia and mental defect, epicanthus and ptosis, deaf mutism, hereditary icterus, albumin, and several examples of digital malformations.

The last chapter is devoted to a discussion of the significance and mechanism of the hereditary element in disease. The conclusion is that "the study of human genetics should become part of the work of State medicine." There can be no doubt whatsoever that properly recorded pedigrees, supported by accurate post-mortem examinations would help enormously in diagnosis and prognosis. The danger of an over-enthusiastic interest in human genetics is that, having recognized that the hereditary constitution plays an exceedingly important part in the incidence and distribution of defects, one is tempted to advocate the eradication of disease through the eradication of defective germ plasma. Thus, though theoretically quite sound as a policy, it is impossible in practice. Humanity is loaded with hidden undesirable recessives, and the problem which cannot be solved by the application of genetic methods to mankind is the identification of the carrier.

Would that there were more general practitioners of medicine like the author of this book! We know so little about human heredity for the simple reason that the practitioners have known so little about the science of genetics. Material which would have provided most valuable knowledge concerning the mechanism of heredity and variation in man has been passed by unnoticed. This book, written by one general practitioner for his fellows, will benefit them not only intellectually, but also professionally.

THE CHILD IN PRIMITIVE SOCIETY

A reasonable scepticism is desirable in the ordinary reader of most books on folklore, anthropology, and pre-history. This is true, neither in greater nor less degree than the average, in respect of Dr. NATHAN MILLER's volume in the Library of Educational Psychology entitled *The Child in Primitive Society*.¹ Dr. Miller supplies the reader with a multitude of facts concerning many aspects of child life under savage or primitive conditions, but he is himself careful to warn his readers of the necessity for distinguishing between the objective facts and the views, opinions, rationalizations, and beliefs of primitive peoples as to the worth and meaning of these facts. It seems equally desirable to distinguish from the facts and from the primitive views and beliefs about them, the explanations given by modern writers about both, and such theories as are built upon these explanations. It is so easy to invent certain aspects of the past and to credit primitive man with a powerful and prolific imagination and an amazing gift of intuition or observational inference from the phenomena of nature of which there is but little real evidence in the average members of the under sections even of modern societies, with some six thousand years of civilization behind them. Contradictory explanations can, of course, often be given of the same belief—instances will easily be found in Dr. Miller's book—but it is unlikely that they can all be true of the same belief in the same society. The contradictions of some more generalized statements are equally disconcerting. It is said that the social forces in primitive society are as yet so scanty and poor and insignificant that the child does not gain much survival-value from them, and again, that they are impressed upon the child so definitely and strongly that it is almost impossible for him to escape them or continue to survive if he departs from them. Later it is stated that the suggestive social contacts and influences of modern life are so numerous with the civilized child, especially during his formal education, that he can scarcely escape being stereotyped in one mould, and again, that it is the absence of these same numerous influences which places the primi-

tive child at a disadvantage in regard to individual development and differentiation. From Dr. Nathan Miller's book, then, as with other books of a similar type, it is difficult to gather any consistent or practically valuable conclusion. Nevertheless, it is an interesting and very able study of the place of the child in the history of society. It is a singularly complete survey of its subject in logical order. It traces the gradual fashioning of the child's social existence by primitive forces, customs, and methods, many of which are shown to have survived in some degree as parts of our modern educational systems and it contains many incidental observations and suggestions which may well bear fruit in the minds of teachers, sociologists, and others who will be glad to read it.

SYMPTOMATOLOGY

When a book has been through a number of editions it may safely be assumed that not only does it supply a popular want, but that it fulfils that role adequately. Of such a select company is *The Use of Symptoms in the Diagnosis of Disease*, by Dr. HOBART AMORY HARE, the ninth edition of which has recently been published. It is not difficult to discern why such a treatise should prove so obviously acceptable, as the author explains that the book is written upon the plan which is actually followed in practice—namely, the building up of a diagnosis by grouping the symptoms. A very extensive index with many cross-references in itself often gives the clue to the diagnosis without the necessity of turning up the text. Not that there is the slightest suspicion of the cram book about this volume, or of any such catchpenny claims as diagnosis made easy. On the contrary, the why and the wherefore are described and discussed with sufficient breadth and clearness to be of real scientific help in arriving at the truth in any difficult and obscure case. The chapters are well written and the text bears the stamp of the experienced physician who is keen to restore once more the clinical worker to his proper position as one self-reliant and confident in his own powers of observation, and not dependent every time for a ready-made diagnosis from the laboratory, though at all times willing to profit by laboratory assistance, as every good physician must be. Dr. Hare gives some shrewd advice upon the management of the patient, and what is perhaps of still greater importance, the skilful handling of the relatives and friends. This edition of a popular book should prove as successful as its predecessors have been.

NOTES ON BOOKS

The Medical Directory for 1929² exceeds the size of its immediate predecessor by nearly fifty pages, this is largely due, no doubt, to the fact indicated in a table near the beginning, that the numbers of the medical profession have increased from 53,289 last year to 54,146 in the present edition. Small reductions occurred in Scotland, Ireland, and the Services, but these were more than balanced by a large increase in the Provinces and a smaller increase in London. The present addition of 857 names compares with 731 in the previous year. In each of the four preceding years the increase was over 1,200 reaching a peak in 1926, when it was 1,802. The general contents of the *Medical Directory* are arranged on the familiar lines. Dr. Fortescue Fox again contributes a description of the spas and climatic health resorts of Great Britain, Ireland, and New Zealand, this has been increased in length by a few pages, and is well illustrated. A section on marine health resorts includes a chart of the average sea temperatures during the summer months at certain places. This valuable book of reference (now in its eighth fifth edition) remains as indispensable as ever.

The monograph on genital glands, sexuality, and the central nervous system³ by Dr. OTTO KAUDERS, who is assistant in the psychiatric clinic of Vienna University, forms part of a series devoted to neurology, psychiatry, psychology, and allied subjects. The work is divided into six chapters, dealing

² *The Use of Symptoms in the Diagnosis of Disease*. By Hobart Amory Hare, D.Sc. M.D. LL.D. Ninth edition thoroughly revised. London. H. Kimpton. 1928. (6 x 9½ pp. xli + 528. 12s. 4 plates. 4s. net.)
³ *Medizinische Sexualität und Zentralnervensystem*. Von Dr. Otto Kauders. Berlin. S. Karger. 1928. (Sup. 8vo. 8vo pp. 194. 6 figures. 3.10.83.)

respectively with the internal secretion of the genital glands, experimental sexual biology, relations between the function of the sexual glands and the sexual impulse, the clinical results of experimental sexual biology, the biological principles of the influence of the central nervous system on the genital function and sexual impulse, and the psychical structure of the sexual instinct. A voluminous bibliography is appended.

The *Transactions of the Ninth Quinquennial International Homoeopathic Congress*,¹ held in London last year, has been issued in two paper covered volumes. The first contains public addresses, correspondence and reports. The second (no fewer than 832 pages in length) gives the full text of original communications and discussions.

Dr C. ENDERLE has made an Italian translation of Economio's excellent book on the cell structure of the cerebral cortex of man, of which the French translation was reviewed in the *British Medical Journal* of October 6th (p. 616).

Transactions of the Ninth Quinquennial International Homoeopathic Congress. London: J. Bale, Sons, and Danielsson Ltd. 1928. (64 x 101 illustrated. 31s. 6d. net for the two volumes.)

* *La Citochimica della Corteccia Cerebrale Umana*. Da Costantino Economio. Edizione Italiana curata dal Dott. C. Enderle. Con prefazione del Professore G. Mingazzini. Bologna: L. Cappelli 1928. (Sup. cov. 8vo pp. 192. 61 figures. L. 30.)

PREPARATIONS AND APPLIANCES

A NEEDLE FOR USE IN GAS REPLACEMENT

Dr ALFRED G. CAMPBELL (Birmingham) describes a simplified technique of replacing pleural effusions with gas involving the use of a needle he has specially designed for the purpose. He writes: "The needle consists of a central stem about 2½ inches long, having a packing box in its upper end and terminating in a male screw end to which may be attached any size of hollow needle or cannula that one desires to use. From this two laterals branch off—one on either side and set at the most acute angle consistent with strength and efficiency to the central stem. Both the laterals and central stem are controlled by stopcocks. When a cannula is employed I have found it useful to have the top of the trocar made about 1½ inches longer than necessary and with a button end. This lies in the palm of the hand and gives the operator better control of the instrument when puncturing the chest wall. For this reason when a hollow needle is preferred I recommend a short plug in with a top similar to that of the trocar to be fitted into the upper part of the central stem. Once the pleura has been punctured it is advisable to withdraw the trocar or plug in completely and to close its stopcock. The lateral whose junction to the central stem is nearer the needle point is joined to the aspirator by means of a rubber tube.

the other lateral is joined by a rubber tube to the stem of a Y-shaped metal junction the branches both of which have stopcocks are connected by means of rubber tubing, the one to the gas bottle the other to the manometer. When performing the operation I have found it of great advantage to have the two laterals lying in a vertical plane the one carrying off the fluid being the lower. While the fluid is being withdrawn it is essential that the stopcocks controlling this channel should be the only ones open. Similarly when gas is needed to replace the fluid the stopcocks controlling this channel should be the only ones open and they should be opened only after the others have been closed. The operator can find out if the fluid has fallen to the level of the needle by closing all the stopcocks and then opening only those which control the way between the pleural cavity and manometer. When this fall has occurred the manometer responds in the usual way and a pleural pressure can be obtained. In brief there should be only one avenue communicating with the pleural cavity at any given time during the operation. The chief advantages of the instrument are that a replacement can be carried out by means of one needle and the operator has complete control over the parts leading to the aspirator gas bottle and manometer. The needle has been made for me by Messrs Philip Harris and Co. Birmingham.

PREVENTION OF CANINE DISTEMPER.

THE study of canine distemper initiated jointly five years ago by the Medical Research Council and the Field Distemper Fund is by no means completed, but Dr P. P. Laidlaw, F.R.S., and Mr G. W. Dunkin, M.R.C.V.S., the investigators, in a report issued on November 29th,¹ show that not only have considerable advances been made in our knowledge of the causes of this disease, but that it is now possible safely and effectively to protect dogs against its ravages.

Breeding Susceptible Stock

When the Scientific Committee of the Field Distemper Fund commenced its work there were two views of the pathogenesis of distemper demanding special investigation: one that it was due to infection by the *B. bronchisepticus*, isolated from the majority of distemper dogs by McGowan, the other, suggested by Caird, that the infecting agent was an ultra-microscopic filter-passing virus. Unfortunately, the early research workers never knew for certain whether the dogs used for their tests were actually susceptible to the disease, or whether they had at some time suffered from a mild attack of distemper, recovered, and become immune. This an experiment in which no typical result followed the inoculation of an alleged causative organism could be explained away by supposing that the animal was immune from the first, leaving only the successes to be considered. Moreover, the mode of spread was so little understood that it was difficult to guard against accidental infections during the course of crucial experiments. Dr Laidlaw and Mr Dunkin decided, therefore, that for accurate research it was important to breed experimental animals under conditions that would guarantee that they had never come in contact with distemper infection. In their report they describe how they bred dogs within a ring fence in the strictest isolation, how they removed the parents from the ring as soon as practicable, and did everything possible to prevent infection from gaining access to the susceptible stock. A ritual of disinfecting, bathing, and donning sterile clothing had to be performed by everyone entering the isolated compound in which the dogs were bred, and the number of persons allowed to enter was strictly controlled. A small hatchway was the only means of communication between the building containing the sterilizing room and a storehouse for food, and the interior of the compound, and, apart from the rodenticide oil ration, all food was boiled or autoclaved before being passed through the hatchway. In this way a clean stock of dogs has been maintained for four years without distemper appearing, a fact which may be taken to show that the disease does not arise spontaneously, but that probably all cases are due to transference of infection from one animal to another.

The Arrangements for Experiments with Dogs

In the investigation of such an infectious disease it was necessary to exclude all possibility of accidental infection occurring in the experimental animals. A fly-proof dog hospital was constructed, with arrangements for preventing the conveyance of infection from dog to dog by persons engaged in the experiments. Entrance to the hospital was possible only through a corridor, the floor of which contained constantly three inches of disinfectant solution, and special means were taken to sterilize the hands and clothing of persons entering the building or passing from cubicle to cubicle. By itself, however, this method of preventing accidental spread of infection to healthy controls proved inadequate, probably on account of air-borne infection from cubicle to cubicle. A series of kennels were therefore constructed around the laboratory buildings each surrounded by fencing and about fifteen or twenty yards from its nearest neighbour. In this way it proved possible to keep a susceptible dog for months in one kennel while experiments were carried on in adjacent kennels.

Experimental Distemper in Dogs

Notwithstanding the protean nature and variable severity of the symptoms of distemper, the experimental work has

¹ *The Field*, November 29th 1928, p. 655-658.

indicated that the disease is a single entity, a dog immune to one strain of virus being immune to strains from other sources. The variable symptoms are due in part to secondary infections, which are responsible for much of the sum total of the disease. Broncho pneumonia for example, is not an essential part of the distemper picture, but is due to the invasion of damaged lung tissue by a secondary organism. But under experimental conditions, in which the operation of secondary infecting agents is excluded, distemper develops in its simplest form and runs an uncomplicated course. Such experimental distemper is an acute infectious fever, characterized by an incubation period of four days, a corvina at the outset of the disease, a bi-phasic temperature curve, severe gastro-intestinal disturbance, inflammation of the respiratory tract, and occasionally by the development of encephalitis. It is a disease with a comparatively low mortality rate. The report gives no information as to the late results in the encephalitic cases, since whenever fits were observed the affected animal was destroyed.

Infection and its Spread

The experiments showed that distemper is infective in its first febrile phase, even before symptoms are manifest, that the nasal discharge and the blood are uniformly infective at first, though uncertainly so later and that airborne infection occurs over short distances in confined cases. It is clear that the isolation of infected animals at the earliest possible stage would probably do much to stop the spread of infection. Moreover, since it is exceedingly probable that the crowding together of dogs is responsible for the spread of fatal secondary infections, ample space for animals must be strongly recommended to dog owners.

Distemper in Ferrets

When the investigation was being planned it was deemed desirable to employ some animal other than the dog for certain phases of the work, and for various reasons Dr. Laidlaw and Mr. Dunkin selected the ferret. The ferret is exceedingly susceptible to infection and nearly always dies of the disease, it is therefore unusual to find a resistant animal in a hatch bought in the open market. Furthermore the ferret breeds rapidly and thrives in the rigorous confinement necessarily imposed on experimental animals and controls in the study of such an infectious disease as distemper. And finally owing to the rarity of mild cases of distemper in the ferret, it is a useful test animal in those cases where the diagnosis in dogs remains doubtful. It was found that ferrets which did recover from an attack of distemper proved to be immune to infection not only by the strain of virus which caused the original disease, but also to all other obtainable strains of distemper.

The Nature of the Infecting Agent

Quite early in the course of the experimental work it was clear that the weight of evidence was in favour of Caine's view that the infective agent was an ultramicroscopic organism. The disease can be transmitted to a healthy dog by injecting into it a minute amount of blood or tissue from a diseased animal yet in the great majority of cultural experiments the infecting blood and tissue proved to be sterile. Moreover, infective filtrates were secured when employing filters known to retain all visible bacteria. The data available indicate that the organism is of the same order of size as the organism causing pleuro-pneumonia of cattle. Every effort to secure cultures of the infecting agent has failed, and though efforts to this end are still being made, Dr. Laidlaw and Mr. Dunkin believe it is now doubtful if any satisfactory result can be achieved.

The Immunization of Ferrets

The first experiments in immunization were conducted on ferrets. It was considered probable that any method which proved successful in their case would also be applicable with minor modifications, to the dog. The difficulty was to prepare standard vaccines in the absence of a technique of artificial cultivation of the virus. Experiments showed however that at the height of the disease the spleen of distemper ferrets contained sufficient

infecting agent to make a vaccine which, though of variable and indefinite potency, was in practice effective. The method now adopted is to apply a patency test to a small quantity of filtrate from a 20 per cent suspension of distemper spleen pulp in saline, sufficient formaldehyde being added to the main bulk to yield a final concentration of 0.1 per cent. This formalized spleen suspension is tested for sterility, made non-irritant by the addition of enough ammonium to give a pH of 8.0 to 8.2, and used as a vaccine. It has been found that ferrets can be completely immunized to all strains of distemper virus by a subcutaneous injection of two cubic centimetres of vaccine, followed a fortnight later by an intradermal or subcutaneous injection of 1/4 c.c. of living virus—that is, of approximately 100 fatal doses for an unvaccinated animal. Vaccination with formalized material alone is inadequate to ensure solid and lasting immunity.

Immunization of Dogs

The use of ferret vaccine on dogs proved on the whole to be unsatisfactory. The amount of vaccine obtainable from a small animal like the ferret is not great, and more than a month was required to produce immunization. Efforts were therefore made to produce vaccine from the tissue of distemper dogs. While admitting that the conditions for the manufacture of vaccine of uniform quality were still inadequately defined, and that much has yet to be learned about the optimum time for the collection of the virus tissues to be worked up into a batch of vaccine, Dr. Laidlaw and Mr. Dunkin state that experience of a number of successes and failures makes it possible to form a good idea as to which tissues should be used for the preparation of vaccine in any given case. The results with a good batch of vaccine made from distemper dog tissue are most remarkable. A single dose of 5 c.c. of vaccine administered subcutaneously will induce such a degree of resistance in the recipient that a large dose of virulent virus injected after one week produces very little effect. Moreover, dogs which have been immunized by vaccines followed by living virus resist large doses not only of one strain, but of all strains of distemper. They may be placed in contact with acute cases of the naturally occurring disease and remain uninfected. The results seemed so good that work with privately owned hounds and dogs was undertaken, with uniformly good results. 325 couple of hounds belonging to fifteen different packs were treated, untreated hounds of the same stock and age running with the immunes, acting as controls. On several occasions distemper has broken out in the kennels and attacked the unvaccinated hounds, but none of the treated hounds have developed the disease.

Both for ferrets and for dogs the homologous vaccine has proved superior to the heterologous, a fact not without considerable theoretical interest. It may serve to prevent undue optimism regarding the use of complex vaccines of this kind under discussion. These may prove to be efficient with one species of animal, but it does not follow that they will be as efficient with other species.

The Future

The complete conquest of distemper is bound up with the successful cultivation of the virus apart from the living animal. Meanwhile it is desirable that the present vaccination method should be made as perfect as possible and as generally available as can be arranged. Quite recently a serum with valuable protective properties has been secured by the injection into the recovered animal of some millions of infective doses on one or more occasions. This serum may prove to be of practical value either in the treatment of disease or in the development of a technique of prophylactic serum virus inoculation. These two lines of investigation—virus cultivation and serum manufacture—have as their primary objective the benefit of the canine population. They may however, shed light on the general problems of acute infectious fevers, and show a way to their correct method of study and to their prevention and control in other animals and in man.

[Questions on this subject were asked in the House of Commons this week, as may be seen by turning to our Medical Notes in Parliament (p. 1118).]

British Medical Journal.

SATURDAY, DECEMBER 15TH, 1923.

BREAST-FEEDING

REFORM in medical thought and practice during the past thirty years is nowhere more plainly seen than in the supervision of childhood, infancy, and the pre-natal state, or, to take a specific instance, in the matter of infant feeding. At the beginning of the century little heed was paid, as a rule, to breast feeding. The slightest difficulty in carrying it out, or even opposition by the mother, resulted more often than not in a prompt resort to artificial feeding. It was the time of the vogue of prescriptions in percentages of protein, fat, and sugar, designed by their authors to suit the digestion and idiosyncrasy of each particular infant. Every now and then a solitary voice was heard in protest, but no leader arose to convince our world of its error, and the path that led to the study of natural feeding was found by one here and one there until the track became worn and clear to all. Now the criterion of success at an infant welfare centre is no longer the number and variety of substitutes for human milk doled out to the mothers, but the low percentage of failures to secure full breast feeding. The progress made during the past decade or so has been clearly indicated by an American observer, Dr F. H. Richardson of New York, whose words may be quoted again in these columns. There has been a steadily increasing tendency on the part of students of infant health and nutrition to concern themselves with some of the multifarious problems connected with the natural feeding of children, as compared with an earlier (and still altogether too prevalent) tendency to experiment with artificial methods of nourishing babies."

The most obvious reform in the ideals of medical practice arises from a general recognition that the chief purpose of Medicine is the preservation of normal function by the removal of disturbing causes, and with this has come a wider realization of the part played by mental stress and adverse social conditions in the production of disordered function and disease. A paper that appears elsewhere in this issue of the *British Medical Journal* not only provides an excellent illustration of these ideals, but by its concentration on the physiological aspect, on the removal of inhibitory factors, on the effect of social environment, and on the disordered function that may arise from psychological causes even in the nursing it shows how the ideals may be translated into everyday practice. Dr Pooler, in his 'Observations on breast feeding,' emphasizes certain points in the physiology of lactation that are of vital moment in practice, especially the value of suction by a healthy infant as a stimulus to adequate lactation, and the importance of securing complete emptying of the breast, with the corollary that additional feeding must tend to lessen secretion. He discusses the inhibitory effect of mental strain, and describes a case of difficulty with a 'neurotic' infant of the type made familiar to us by Dr H. C. Cameron in which an operation for pyloric stenosis was averted by entrusting for three months the services of a foster mother. The reluctance of the mother to hand her child over to a stranger to nurse recalls an incident recorded in *The Cloister and the Heart*!

Charles Reade tells us there how the infant, afterwards known as Erasmus, began to peak and pine when his mother, Margaret, torn with anxiety at the lack of news from her husband, was unable to provide enough milk from her breast. Margaret was as refractory as Dr Pooler's patient at the thought of handing her son over to a foster mother, until she realized that there was no alternative, but she could not bear to 'witness the intolerable sight of another nursing her Gerald, and Gerard drawing no distinction between this new mother and her, the banished one.'

Other common causes of failure are considered by Dr Pooler. Too frequent feeding, by producing loss of appetite and indigestion, results in weaker suction and less stimulation. This sequence is common in the screaming child that is fed irregularly in the hope of obtaining quiet. Another trouble arises when the mother's milk 'goes' after too brief a lying in time, probably due to worry and anxiety following the resumption of household duties, and to the less regular and more frequent feeding of the infant, particularly at night. Increased physical strain, especially if the extra food this calls for is not forthcoming, is mentioned by the author as a possible contributory cause, and underfeeding of the mother is taken up at some length in order to show that this has "some effect, not perhaps on the actual development of lactation, but certainly on its efficiency." So many factors may, however, come in to interfere with the progress of a breast fed child that it is difficult to disentangle from all the others the single factor of under-nourishment of the mother.

Dr Pooler's paper should make a special appeal to all who are engaged in general medical practice, not merely because he is himself one of them, though with special experience in child welfare, but because he presents the clinical aspects of a subject of prime importance in family practice with the intimate knowledge of one who knows the difficulties and how they may be met. His contribution strengthens the argument for the general practitioner taking a prominent place in the service of public child welfare centres.

THE PREVENTION OF DENTAL CARIES

MOST of our readers will be aware of the long series of researches that Mrs. Mellanby has conducted with the object of determining the influence of the anti-rachitic vitamin (vitamin D) on dentition. Ten years ago the Mellanbys noted that puppies in which rickets had been induced by deprivation of fat soluble vitamins showed very imperfect dentition. The teeth of such animals were small and irregular, and frequently discoloured, while histological examination showed that the development of both dentine and enamel was defective. Further research established the fact that this imperfect dentition in puppies was due to lack of the antirachitic factor (vitamin D). In a series of researches Mrs. Mellanby showed that it was possible to produce in dogs dentitions of almost any degree of imperfection desired, simply by varying the vitamin content of the diet. A comparison between the histological characters of these abnormal teeth produced by vitamin lack in dogs, and the structure generally accepted as normal for the human tooth, showed that there was a remarkable similarity between the two. This resemblance naturally suggested that a partial deficiency in vitamin D might be a cause for the dental imperfections that are almost universal in civilized communities. This conclusion was

supported by examination of the deciduous teeth of children. No fewer than 1,036 of such teeth were examined histologically. The general belief has been that the majority of deciduous teeth are normal, but Mrs Mellanby showed that by far the greater number of these present signs of defective development of dentine. Moreover, the teeth obtained from dental clinics were more defective than teeth from children of middle class families. This fact supported the view that defective dentition was due to a dietary deficient in fat soluble vitamins for one of the chief faults in the diet of the poorer classes is the inadequate supply of animal fats.

During recent years Mrs Mellanby has tried to obtain direct evidence as to the influence of vitamin D on the dentition of children. A general summary of her work has appeared in a recent number of *Physiological Reviews*,¹ and the paper written by her and Dr Lee Patterson published in our present issue at page 1079, contains an account of the most recent work on this subject. Previous work had shown that, when children were given cod liver oil, dental caries did not spread in their teeth as rapidly as it did in the teeth of control groups which did not receive the oil. Cod liver oil contains, however, the two fat soluble vitamins A and D, and recent work has indicated that vitamin A plays an important part in maintaining the resistance of the body against infection. This made it important to determine which of the two vitamins played the chief part in preventing caries in the human subject.

In the work reported in the *British Medical Journal* this week only one vitamin was administered—namely vitamin D in the form of irradiated ergosterol. The authors conclude that the addition of this vitamin has a definite effect in checking the initiation of new carious points and in diminishing the spread of old carious points. It may be objected that the number of children under observation was small, and the authors themselves draw attention to the difficulty in obtaining any quantitative measure of the spread of caries. The difficulty of obtaining conclusive evidence in such a problem is, indeed, obvious. Even those who do not accept Mrs Mellanby's results on children as conclusive proof must at least admit that her series of researches on dogs and children considered as a whole establish a very strong probability that the progress of dental caries is largely determined by deficiency of vitamin D in the diet. This alone must be looked upon as an achievement of great promise because it is the first suggestion of any effective means for preventing this complaint. The potential importance to public health of such a discovery can best be realized by considering the total amount of ill health in the community that is at present caused by dental caries.

PAINFUL SHOULDER

A discussion on this subject by the Orthopaedic Section of the Royal Society of Medicine on December 4th brought to the front a very important question. Mr George Perkins opened with an admirably clear exposition of certain forms of painful shoulder following injury, which, in his opinion, might be taken as outstanding types. Briefly stated these were (1) the all too common case of adhesions after sprain, curable by manipulative surgery, (2) a condition which the speaker called by the very doubtful name of "tendinitis," but which has been also described as

"subdeltoid bursitis," curable by incision, (3) a type due to osteoarthritis, which manipulative surgery was unable to relieve, but which generally yielded to heat in any form, graduated faradism of muscles, and sometimes ionization, and (4) a type which was due to a subacute arthritis, with the common symptoms of that affection. The usual local and general treatment for arthritis was more or less efficacious here as elsewhere. All these four varieties might occur after comparatively slight trauma, such as a fall from a few feet on to the shoulder or hand, but they might be disastrously crippling, especially to those who earned their bread by manual labour. The second type attributed by Codman to subdeltoid bursitis, was sometimes accompanied by excruciating pain comparable in severity to that of biliary colic. Its diagnosis was easy, because pain on movement was only felt through a small arc of abduction about the middle of the range. This symptom Mr Perkins explained by the supposition that the inflamed insertion of the tendon of the supraspinatus muscle was squeezed against the acromion during this phase of movement only. The symptoms disappeared in time, so that any prolonged treatment generally proved in cure. As so often happens in such debates, the subsequent speakers did not strictly adhere to the basis of discussion laid down by the opener. Mr McEneaney, indeed, criticized from a philological point of view the introduction of the word "tendinitis" and frankly confessed his inability to discuss the osteoarthritic variety of shoulder pain, because he did not know what was meant by osteoarthritis of the shoulder. Other speakers were inclined to follow their own predilections into the consideration of those conditions which had most interested them, so that Mr Perkins had no hard task in replying to his critics. All the speakers were, however, agreed as to the importance industrially of apparently slight injuries of the shoulder and of the generally unsatisfactory results of outpatient treatment. Dr Alexander Mercer, drawing on his wide experience as medical referee of a large insurance company, impressed the meeting greatly by the statement that of over eight hundred cases of minor injury of the shoulder referred to him, 45 per cent were admitted to be totally disabled temporarily and 11 per cent permanently. It must be remembered that, as Dr Mercer explained, these percentages belong, not to the whole number of cases primarily injured, but to the number of cases which did not recover at once, and were therefore referred to him. The general consensus of speakers strongly supported the opinion expressed by Mr Alan Todd some time ago, and repeated in this discussion, that all shoulder injuries, including dislocations, should be treated in the abducted position, in which the inner bag of the capsula of the joint is kept stretched and prevented from falling together in folds and becoming contracted, especially when it had been torn or bruised. His comparative figures of the duration of treatment by abduction and other methods were strikingly favourable to the former. It is clearly necessary that apparently slight injuries of the shoulder should be more seriously and thoroughly treated but the adequate provision of such treatment is impossible in the overtaxed wards of a general hospital. As in the case of the treatment of fractures, it is to the Poor Law hospitals that we must look for satisfactory treatment when their staffs have been made adequate in numbers and their equipment and the training of their personnel have been brought up to date. A big male adult whose arm is fixed in the "straphanger" position by a plaster splint is apt to be an awkward inmate of any household, and is an impossible denizen in a workman's cottage or flat. The "stitch-in-time" week spent as in-patient may save nine or more as an out-patient, and be an economy to all concerned.

HEALTH OF THE NAVY

THAT the Admiralty is making a praiseworthy effort to bring its medical statistical reports up to date is shown by the fact that the report for 1926¹ has appeared less than a year after that for 1925. We still think that the first part of these reports might be considerably reduced in bulk, since it mainly gives in words what is later found in statistical tables. A brief commentary on the several diseases and injuries would be more useful, and certainly more interesting, than the present repetition of figures. The report for 1926 deals with a total strength of 90,650, representing an increase of 700, and the rate of admission was 459.86 per 1,000, a decrease of 4.92 as compared with the previous year. The average number of men sick daily was 20.45 per 1,000, a decrease of 1, the death rate was 3.18 per 1,000, an increase of 0.36, and the number finally invalided, 1,643, a ratio of 18.12, shows an increase of 2.43. As in previous years, the chief causes of admission to the sick list were injuries (6,967 cases), catarrh (5,636), gonorrhoea (3,975), and tonsillitis (2,959). Over 21,000 vaccinations against small-pox were carried out, and only one case of small-pox, on the China Station, is reported, the man had been successfully revaccinated four years previously. Influenza was of a mild type, and there were no deaths from it. There were decreases in the incidence of pneumococcal infections and rheumatic fever. One case of cholera occurred on the China Station, and was successfully treated with Tomb's essential oil mixture. The cases of tuberculosis, also showing a decrease in 1926, are now divided into two classes—pulmonary and non-pulmonary. The Africa Station shows the highest rate and the East Indies Station the lowest, but nothing can be deduced from this fact because of the small numbers on these foreign stations, last year the East Indies Station showed the highest rate. The ratings mostly affected were writers, marines, cooks, and supply staff—an entirely different incidence compared with 1925, but still pointing to the susceptibility of those working between decks. A new feature is the tabulation of cases of pulmonary tuberculosis according to the type of ship or establishment in which they occurred, and also according to age, and it is probable that useful information will in time be derived from the former table. Venereal diseases again show a decrease, the anti-venereal pocket outfit now consists of calomel cream and mercurio iodido soap. Diseases of the respiratory and digestive systems show a decline. General injuries account for 279 cases, with 2 invalidings and 120 deaths, of which 84 were occasioned through the loss of H. M. S. *Valerian*. Local injuries also show a decrease. Twenty-eight cases of wounds in action, with 7 deaths, are recorded, 25 of these occurred during troubled conditions in China. There were 12 cases of suicide and 34 of alcoholism. Dental work in the navy continues to be performed with very satisfactory results. The total number of deaths in the navy was 289, the chief causes being suffocation by drowning (104), injuries (36), and diseases of the intestines (15). The chief causes of invaliding were diseases of the eye (370), diseases of the ear (242), tuberculosis (195), deformities of limbs (84), injuries (83), diseases of the heart (78), and neurasthenia (70). Only 43 men were invalided on account of venereal diseases. An interesting table comparing the health of the two training establishments for boys, *Impregnable* (hulk) and *Ganges* (shore building), shows that in the former there was less infectious disease, less rheumatism, and less digestive trouble, but more pneumonia and more respiratory disease in general. The incidence of tuberculosis was, however, approximately the same in both.

HERBALS IN ANTIQUITY

As is his wont, Dr Charles Singer has contributed a most instructive and beautifully illustrated article in dealing with "The herbal in antiquity and its transmission to later ages." It begins with the iconoclastic statement that most herbals are devoid of any rational basis, and that their authors, being incapable of treating evidence on scientific lines, make a direct attack on disease without any "nonsense about theories," the aim of such treatment being exclusively *practical*—"a vague and foolish word with which, from the days of Plato to our own, men have sought to conceal from themselves and from others their destitution of anything in the nature of general ideas." Discussing the relation of herbals to pharmacopoeias, Dr Singer points out that originally the latter word meant a drug compendium, and not a drug list, the modern usage in England dating from the seventeenth century. Professor Ralph Stockman, however, writing thirty years ago on "The literary sources of our pharmacopoeia,"² stated that the word first appears in 1561, when it occurs twice—in the *Compendium Pharmacopoeae Joannis Placotomi*, Lyons, 1561, and in Anutius Foesius's *Pharmacopoea medicamentorum omnium, quae hodie in officinis exstant*, etc., Basel, 1561. But Dr Singer's subject is herbals in early times, and he passes in review the earliest Greek herbal known, that of Diokles of Karystos (circa 350 B.C.), that of Theophrastus (circa 372-287 B.C.), Herophilus of Alexandria (300 B.C.), Nikander (200 B.C.), Krates the rhizotomist, who was both physician to Mithridates VI Eupator (120-63 B.C.), poisoner and compounder of antidotes. Krates (circa 75 B.C.) was the first to illustrate his herbals, and thus exerted great influence, not only on the development of the herbal, but also on the course of scientific botany. "The most influential herbal ever written" is that of the army surgeon Pedanios Dioskurides of Anazarba (circa A.D. 50), which, like those of Galen and Oribasius (A.D. 400), was subsequently translated from the Greek into Latin. Of the numerous manuscripts derived from the herbal of Dioskurides, the earliest and most notable is the *Juhana Amica*, about which Dr Singer gives much scholarly information. The Johnson papyrus, discovered in Egypt in 1904, and probably dating back to the fourth century, was derived from the same or a similar Greek original as the herbal commonly ascribed to Apuleius Platonius, which is the most important of the Latin series. There are many manuscripts of the Apuleian herbal, and their influence, as shown by the illustrations, can be traced through Anglo-Saxon productions into modern times.

DISEASES OF THE JEWS

In delivering the first series of the William Sydney Thayer and Susan Read Thayer Lectures in clinical medicine³ at the Johns Hopkins Hospital last summer, Sir Humphry Rolleston dealt in his first lecture with the hereditary factor in some diseases of the haemopoietic system. In the second lecture he continued his examination of heredity by describing some diseases to which the Jewish race is especially susceptible. Some of these diseases, such as amaurotic familial idiocy and thrombo-angitis obliterans, are chiefly seen in, though not absolutely confined to, Jews, they appear later in life and less severely in Gentiles, thus suggesting that the inborn tendency is more powerful in those with a Hebrew heritage. In other diseases, such as obesity and diabetes mellitus, the influence of heredity is masked by other possible factors. Thus it has been suggested that there is a form of obesity which is due to

¹ Singer C. *Journal Hellenic Studies* xlvii.

³ Reprinted from the *Bulletin of the Johns Hopkins Hospital* Baltimore 1928 vol. xliii, pp. 61-69, 117-133.

familial tendencies, in which diabetes is not likely to supervene, but that diabetes is prone to occur in cases of obesity due to excessive and unsuitable food or to endocrine disorder. The lecturer recalled that Joslin has stated emphatically that a Jew becomes diabetic, not in virtue of his race, but because he is a fat Jew. At the same time, Joslin's statistics lend some support to the hereditary or familial factor in diabetes in Jews. Whether the frequency of obesity, and so of diabetes, in the Hebrew race is entirely acquired and due to wealth and luxury, or whether it is, in part at least, hereditary and constitutional, is still a matter of doubt. Acromegaly has been thought to be more common in Jews, but in this case the observation itself seems open to doubt, although Sir Humphry Rolleston is under the impression that there is a decided tendency to some excess of anterior lobe pituitarism in the Jewish race. At the end of the lecture brief reference was made to malignant disease, tuberculosis, and alcoholism in Jews. It was noted that uterine cancer, especially of the cervix, was rare in Jewesses, though malignant growths in other regions were as frequent as in Gentiles, perhaps more so. The comparative resistance of Jews to tuberculosis has been ascribed to acquired racial immunity, to more careful inspection of food, to greater sobriety, to comparative freedom from syphilis, and to care of the children. In the opinion of the lecturer the sobriety of the Jews, and the resulting freedom from alcoholic diseases, did not depend on an inborn trait, but were the result of moral and social influences. Abstemiousness is, however, said to be a noticeable trait among Jews who are not subject to the moral and social influences of their race and religion. The general impressions to be gathered from the lecture are that there is still much observation and statistical investigation to be made in those diseases to which the Jewish race is susceptible, and that medical nomenclature is becoming burdened with some horrible expressions, such as the Laurence-Moon-Biedl syndrome and lipid-celled spleno-hepato-megaly. Perhaps, however, such names may help to deter the careless from excess, and heavy smokers, especially of cigarettes, may take warning that their habit, particularly if they are Jews, may make them victims of thrombo-angitis obliterans.

THE ABC OF HOSPITAL ACCOUNTING

MEMBERS of boards of management and of the administrative staffs of hospitals in all parts of Great Britain owe a debt of gratitude to the King Edward's Hospital Fund for London for the light thrown by various publications of the Fund upon problems which are their particular concern. An account was given in the *Journal* of October 27th (p. 771) of the annual statistical report of the Fund's Hospital Economy Committee, which presents not only a general survey of the financial position of the London hospitals, but detailed analyses of their income and expenditure, affording valuable material for the enlightenment of those engaged in "making ends meet." The prerequisite of the report is, of course, the employment by all the institutions concerned of the Fund's "Revised Uniform System of Hospital Accounts"—a title which is self-explanatory. This system is in use, as recommended by the Voluntary Hospitals Commission, in many hospitals outside London. It has been recognized, however, that the adoption of the full system may be impracticable in the smaller hospitals, and the Fund has therefore now published, in pamphlet form, *Accounts for Small Hospitals*, containing an explanation of a simplified form of the "Revised System." It has been prepared by a subcommittee under the chairmanship of Sir Basil Mayhew, and gives with the utmost clarity a concise summary of the basic methods of hospital accounting, with

a reasoned statement of the case for uniformity of practice. The intention has been, in particular, to meet the needs of honorary officials engaged in hospital administration without clerical assistance who have neither the time to study the details of the "Revised Uniform System" nor the knowledge of accountancy necessary to profit thereby. To such persons, and to those also who may have a specialized knowledge of accounts, but who are at present employing systems not based on any accepted model, the Fund's pamphlet should prove invaluable. It may be commended, further, to those who are interested in any way in the hospitals, and who desire to gain a knowledge of finance sufficient to enable them to read accounts intelligently and to appreciate the problems associated with management. The general adoption of this system would, it is clear, facilitate accurate comparison between one institution and another, and make it possible to secure exact statistics for the hospital work of the country as a whole. The pamphlet may be obtained from the offices of the King Edward's Fund, 7, Wallbrook 1 C 4, price 2s. 2d. post free.

ERNST BRÜCKE

THE names of men famous in the history of medicine are too often regarded as mere labels marking successive steps in the progress of the science, while the discoverer in his human aspect, and as something more than a mere instrument of discovery or piece of laboratory apparatus, falls into the background. Much is to be learnt, however, from a study of the character and mentality of those to whom science is indebted for its progress. Numerous instances could be given of important discoveries made through the observation of simple, uncomplicated facts, involving, as it would appear, no special mental qualifications, and depending, apparently, on the discoverer's manner of outlook on things and his mental habits and interests generally. The study of these characteristics should prove as profitable as an impersonal study of the principles of research. Accounts of the private life of famous men, such as that of Brücke¹ recently published by his grandson, are therefore welcome. Brücke lived in the days when specialization was hardly known, although essentially a physiologist, the diversity of his interests was remarkable even in those days, and he may almost be regarded as a reflex of the encyclopaedists of the eighteenth century. Yet the diverse subjects on which he worked were, as his biography shows, connected by simple and natural links. His early interest in optics he probably gained from his friend Helmholtz, leading to researches on the tapetum of the vertebrate eye and the action of the ciliary muscle; he subsequently studied the absorption of various rays by the transparent media of the eye, and the phenomena of colour sensation. Investigation followed on the colours of opaque media and on the colour changes in chameleons and cephalopods; this naturally led to the examination of pigment cells, of the mechanism of movements in plants, and of muscular contraction, especially in reference to the influence of the duration of the stimulus. His studies of cells inspired him to elaborate a new scheme of cellular structure in opposition to the prevailing scheme of Schwann, while his interest in colour was extended even into industrial matters, and he laid down the principles of colour combination for the guidance of workers in fabrics. It was but a short step from colour to artistic form, and one of the last of his researches was the enunciation of the underlying principles of the beautiful in art. Brücke was, withal, a man of sound common sense, and peaceable in his relations with all his colleagues save Hyrtl, his advice was sought and valued in collegiate and municipal affairs.

LEAGUE OF NATIONS HEALTH COMMITTEE

Among the matters to be considered by the Council of the League of Nations at its meeting at Lugano, which opened this week, is the report on the last session of the Health Committee. A summary of the agenda for this session was published in the *Journal* of October 27th (p. 761) from which it will be seen that the Committee's deliberations covered a very wide field. Reports were received from various commissions and conferences, including those engaged in inquiries relating to infant mortality, malaria, and B.C.G., to which frequent reference has already been made in these columns. The Health Committee endorsed the view of the commission on small-pox and vaccination that the occurrence of cases of post-vaccinal encephalitis is so rare that "they afford no reason to contemplate any restriction of the use of vaccination, which remains the most powerful weapon against small-pox." It appeared to the commission that the occurrence of this complication did not depend upon the use of any particular method of vaccination or of any particular vaccine. The cancer commission reported that an exhaustive inquiry into the methods and efficacy of the radiological treatment of cancer of the cervix of the uterus is being carried out at the Fondation Curie in Paris, the Universitäts-Frauenklinik in Munich, and the Radiumhemmet in Stockholm. It is expected that the report will be ready early next year. The Italian members of the commission are making a study of the relationship between cancer and the bodily constitution, and an inquiry into occupational cancer is being undertaken in conjunction with the International Labour Office. Arrangements for the prosecution of research into the problems of leprosy are in progress, and in this connection, as in other fields of effort, close relations have been established between the League Health Organization and the health services of Latin America. The Committee has approved the programme of interchanges and study tours for public health officials for 1929, interchanges will relate to rural hygiene, the study of sanitary engineering, certain aspects of housing, industrial hygiene, and milk supply. Other matters dealt with by the Committee included the organization of epidemiological intelligence, which is making satisfactory progress, the application of the Geneva Opium Convention, inquiries into the serodiagnosis of syphilis, and education in hygiene and preventive medicine. The general lines of work for 1929 for the Health Organization were defined.

SILICOSIS

The Home Secretary has appointed a committee to advise as to the medical arrangements which could be made for the diagnosis of silicosis (including silicosis accompanied by tuberculosis) in cases of claims arising under the Workmen's Compensation Act, and for carrying out any periodic or other medical examinations of workers which may be prescribed for any industry or process involving risk of silicosis under the Factory and Workshop Act, 1901, or any other enactment. The members of the committee are Mr. J. C. Bridge, F.R.C.S. (chairman), Dr. F. J. H. Contts, C.B., and Professor Arthur Hall, M.D., F.R.C.P. The secretary of the committee is Mr. E. Field, of the Home Office, to whom all communications on the subject should be addressed.

We regret to announce the death, on December 8th, at the age of 73, of Sir John Phillips, M.D., F.R.C.P., honorary physician to the Queen and consulting physician to King's College Hospital.

Owing to the Christmas holidays our issue dated December 22nd will go to press on Tuesday, December 18th, and that dated December 29th on Monday, December 24th.

THE KING'S ILLNESS

ANOTHER week of tense anxiety has gone by since we were able to publish an authoritative review of the course of His Majesty's illness up to the evening of Wednesday, December 5th. The medical bulletins posted twice or three daily at Buckingham Palace have kept the public informed, with most commendable frankness, regarding the local signs in the chest, the general symptoms, and the patient's reaction to the strain of a very severe and exhausting infection.

We need not recapitulate here the bulletins, which have been published in every daily newspaper, displayed at post offices, and broadcast by wireless. They have recorded the fluctuations of an extremely virulent malady which would have taxed the strength of a man of powerful physique in early life. The following statement, which has been authorized for communication to the medical profession, gives an account of the situation up to 3 o'clock on the afternoon of Wednesday, December 12th. The operation of drainage referred to in the second paragraph of this statement was performed by Sir Hugh Rigby shortly after 7 o'clock that evening under general anaesthesia.

"To make clear the nature of this long and exhausting illness, it is necessary to state that a general blood infection and toxæmia were in the first two weeks prominent features and caused at one time grave anxiety. Moreover, the case has not presented the characteristics of a typical pleuro-pneumonia. Seven days ago the evidences of general infection had become less prominent and the blood cultures were sterile, though all medical men will know that sterility of blood cultures is not conclusive evidence that general infection has ceased.

"During the last five days the temperature has again risen to a higher level, yet the pneumonic and pleural signs became at the same time less marked and neither pleural puncture nor study of new and excellent radiograms disclosed any appreciable effusion. Seeing, however, that the original pleurisy had involved the diaphragm, a careful watch has been kept for the formation of fluid between the lung and the diaphragm and its extension to the posterior pulmonary surface. This morning there were signs of this development accompanied by an increased leucocytosis. By exploratory puncture at the extreme right posterior base purulent fluid was obtained which contains organisms morphologically resembling those previously found in the blood stream. Drainage will now be performed. Though this pleural localization of the infection, so anxiously anticipated and looked for, makes the direction of advance more defined and hopeful, there is still in prospect a long and difficult struggle."

The anaesthetic was administered by Dr. Francis Shipway, and within an hour of the successful completion of the operation a bulletin was issued announcing the result. On Thursday morning it was announced that the King had had some sleep during the night, and that the local condition was satisfactory. Though the weakness and toxæmia were considerable, the pulse was steady and His Majesty was not losing ground.

At its meeting on December 12th the Council of the British Medical Association, before proceeding to business, adopted a resolution, proposed from the chair, expressing in loyal terms the deep sympathy of all the members of the Association with their Patron the King and the Royal Family, and their earnest hope for His Majesty's early and complete recovery.

Scotland.

Gifts to Edinburgh University

INTIMATION has been received by the Court of the University of Edinburgh of two substantial gifts for the endowment of a department of surgery. Of the total of £15,000, £10,000 has been given by the Rockefeller Foundation and £5,000 by Mr. Thomas Conan of Leith.

Gynaecologist to the Edinburgh Royal Infirmary

At a meeting of the managers of the Royal Infirmary on December 3rd, intimation was received of the retirement of Dr. William Fordyce, who was appointed assistant gynaecologist in 1906 and gynaecologist in 1921, and who now retires under the age limit. The managers, in recognition of his valuable services to the Infirmary, invited him to accept the position of consulting gynaecologist to the Infirmary, and minutely then appreciation of his work. Dr. James Young, as assistant gynaecologist, now becomes gynaecologist in charge of a ward, and Dr. Ernest Charles Lohm has been appointed assistant gynaecologist.

New Glasgow Professor

The Cairdner chair of physiological chemistry in the University of Glasgow has been filled by the appointment by the University Court of Professor Andrew Hunter of Toronto. The chair was recently rendered vacant by the promotion of Professor Cathart to the regius chair of physiology in succession to Professor D. Noel Paton. Professor Hunter graduated M.B., Ch.B. at Edinburgh University in 1901, and, after a period of postgraduate study at the Universities of Berlin and Heidelberg, was appointed assistant professor of biological chemistry at Cornell University, U.S.A., and later professor of biological chemistry in the University of Toronto. The new professor is expected to take up his duties at Glasgow early next year.

Notification of Chicken-pox

In view of the recent outbreaks of mild small-pox, the Scottish Board of Health has issued a circular under the Public Health (Chicken-pox) Amendment Regulations (Scotland), 1928, continuing the regulations previously in force, and making chicken-pox a notifiable disease for two years until December 31st, 1930.

Extension of Stobhill Hospital, Glasgow

Sir John Gilmour, M.P., Secretary of State for Scotland, on November 30th opened the new electro-medical department which has been erected by the Glasgow Parish Council at Stobhill Hospital. In declaring the new wing open, Sir John Gilmour said that a great hospital like that of Stobhill, which dealt with the poor of the country, was leading the way and pointing to what he hoped, in course of time, might take place in other parts of the country. He thought that whatever differences of opinion might exist with regard to detail in hospital administration it was only by some measure of centralization and pooling of resources that they could extend to all ranks and classes of the country the latest results of scientific treatment. The linking up of public authorities and private hospitals could, in his opinion, be effected for their mutual benefit, but he would be sorry if anything in that linking up were to lessen the interest of the private individual or stem the contribution of the private citizen. Stobhill Hospital, which is under the control of the Glasgow Parish Council, supervised by the Scottish Board of Health, is the largest hospital in Great Britain, having accommodation for 1,900 beds, with a staff of over 500. The new department which has just been opened has been built and equipped at a cost of £40,000, and provides accommodation for x-ray and sunlight treatment, massage rooms, operating theatres, and eye, ear, and dental departments. A new pathological department, mortuary, and chapel have also been added. The hospital was built twenty-six years ago, and during the war was used as a military hospital, where at one time over 3,000 patients were treated in the hospital and in temporary buildings in the grounds. It returned to the control of the parish council in 1920, and since then has been used not only for Poor Law cases, but also for the reception of contributing patients from various parts of Scotland.

England and Wales.

Birmingham Medical School Retirement of Mr. W. F. Haslam

A PRESENTATION of a silver tray and a cheque was recently made to Mr. Haslam on his retirement from active service in the Birmingham Medical School. Mr. Haslam held a succession of offices since his appointment to the staff of the General Hospital in 1882, and was dean of the Faculty of Medicine in the University of Birmingham from 1919 until his resignation in May last. The silver tray presented to him was inscribed as follows: "Presented (with a cheque) to William Frederick Haslam, M.B., F.R.C.S., by colleagues and friends in the University of Birmingham on his retirement from his office of Dean of the Faculty of Medicine, a token of affection and gratitude for valuable services to the Medical and Dental Schools and the University during a period of forty-six years, 1882-1928."

London School of Medicine for Women

The annual dinner of the London (Royal Free Hospital) School of Medicine for Women was held at the Savoy Hotel on December 6th, when Professor Winifred Cullis, D.Sc., presided over a very large and happy reunion. In proposing the toast of "The School and Hospital" Mr. John Buchan, M.P., recalled his experience in connexion with the concentration camps for women and children when he was a young man in South Africa with Lord Milner. He had learned there two lessons which he had never forgotten—one the unassessable value of the self-sacrificing work of doctors and nurses, who in six months turned what had been a lazaret-house into a health resort, and the other the equally unassessable value of the work of women for a women's committee, under Dame Millicent Fawcett, had helped to turn the tide. The Royal Free Hospital, which was about to celebrate its hundredth birthday, was one of the most progressive and best equipped in the land. The London School of Medicine for Women was only half the age of the hospital, but it also had taken rank among medical schools for high efficiency. It precluded the only two equities—namely, that based on competence. It had opened to women a way into a profession for which they were peculiarly fitted. Its history was a continual evolution of hard work, patience, optimism, and good sense. He hoped that when the school in its turn reached its centenary it would be able to look back even upon its present proud position as nothing more than the day of very small things. Professor Winifred Cullis, in responding, expressed gratitude for the generous donations which had made it possible for the hospital to provide further facilities, notably a dental institute, which would form the basis of a magnificent dental school for women. She noted with pride that a past student had contributed £10,000 towards a nurses' block, and she hoped that other old students would follow suit, in recognition of the fact that women would not be in their present position in medicine had not the Royal Free Hospital opened its doors to them fifty years ago. Another definite step forward was in the teaching of psychiatry, for which arrangements had been made with one of the large mental hospitals. Research work was also being undertaken in connexion with the treatment of cancer by radium. She went on to allude delicately to the exclusion of women students from some of the hospitals of London, a step which those at the London School of Medicine for Women greatly deplored, because it might be interpreted as a slur upon women and upon the way they had worked at the hospitals. In conclusion, she referred to the proposed inauguration of an Old Students' Association, through which it was hoped to be able to approach old students and obtain from them a definite and considered opinion on certain lines of policy. Lord Riddell proposed the health of "The Guests," naming many of them, and Miss Brock, the well-known educationist, and Major Ian Hay Beith, better known as "Ian Hay," responded to the toast. Lady Biscoe proposed the health of the chairman, saying that Professor Cullis was one of the forces making for international friendship because of the work she had done on the International Federation of University Women. Those who had worked with her in the

laboratories saw a more intimate side of her character, in her never-failing kindness and consideration for all with whom she came in contact. The chairman, in responding, paid a tribute to the two secretaries, Dr. Halden-Davis and Miss Widdows, whose excellent work had made the pleasant evening possible.

Metropolitan Asylums Board and the Local Government Bill

The Metropolitan Asylums Board, at a meeting on December 8th, received and adopted a report from the General Purposes Committee regarding the Local Government Bill now before Parliament. Under the bill, it will be remembered, the Board will cease to exist, and its functions will be transferred to the London County Council. The report refers to proposals to this effect which have been before the Board on three occasions in recent years, when it has consistently urged objections to them. On the last occasion, in May, 1926, the Board accepted the view that the London County Council would find it impracticable to undertake such an addition to its duties if it were intended that the existing close contact between the elected representatives of the people and the work to be transferred should be maintained. It was decided to inform the Minister of Health that the Board's experience had shown that the management of the central public health institutions of London was of sufficient importance and extent to justify the existence of a central body endowed with statutory powers on which the bodies dealing with local affairs in London should be adequately represented. The report then recalls that the Minister, in January, 1927, received a deputation from the Board, which laid before him in detail its views on his proposals, and that the Minister stated that these views would receive consideration, the next step was the issue, in July last, of the White Paper containing a forecast of the proposals contained in the bill. The Board adheres to the views previously expressed as to the transfer of its powers to the London County Council. Since its inauguration, it is pointed out, the Board has enlisted the services of a large number of men and women who have devoted themselves to the work of providing, maintaining, and extending where necessary the public hospitals required by London for infectious diseases and tuberculosis, mental hospitals, ambulance services, etc. Practically the whole of the debt of nearly £7,000,000 raised to meet capital expenditure has been paid off. The Board has now under its control some 25,000 hospital beds, and in times of pressure employs a staff of 10,000 persons. It is to be involved, the report proceeds in the changes through no shortcomings of its own; on the contrary, tribute has been paid by the Minister of Health and the London County Council to the efficiency of its organization. The members of the Committee finally express the view that the inclusion in the bill of proposals for the abolition of the Board may well be viewed by the people of London with regret, and that the Board should express to the Minister of Health its own regret that its representations have not succeeded in bringing about any modification in his proposals so far as they affect the Board.

Cost of Tuberculosis Treatment.

The Ministry of Health has issued a memorandum (122B/T) showing in tabular form under various headings the weekly cost for each patient at various residential institutions for the treatment of tuberculosis in England and Wales during the year ending March 31st, 1928. For the purpose of comparison the corresponding figures for the previous two years have been included where these are available. The tabular arrangement resembles that in former years, except that provision is made for classification of the cases more in accordance with the records prescribed in memorandum 37/T. It is hoped that the information thus provided will give substantial assistance to the authorities concerned in determining whether their own institutions are being conducted as economically as is compatible with efficiency. The importance of keeping beds filled is emphasized, and it is suggested that local authorities may well revive from time to time the question of staffing which has an important bearing on the cost. When all the beds in an institution are not required for patients from the area served it is advised that efforts be made to obtain patients from the authorities of other areas.

Correspondence.

THE FRACTURE CLINIC THE OTHER POINT OF VIEW

Sir,—Professor Hey Groves, in his presidential address to the British Orthopaedic Association (*British Medical Journal*, December 1st, p. 993), sets out very clearly the arguments in favour of improvement, both of our organization for the treatment of fractures and of the methods of teaching fracture technique in our teaching hospitals. Briefly, he advocates the formation in each of our larger hospitals of a special clinic in which cases of fracture shall be segregated under the charge of one surgeon, with a small, highly specialized team working under him. This was the method found so satisfactory and efficient in the latter years of the war, and the method which Sir Robert Jones advised in an address on the subject (*British Medical Journal*, May 16th, 1925).

No one acquainted with the facts will deny the necessity for the improvement in our present methods of treatment. Speaking generally, organization has lagged behind the necessities of the situation. Methods have changed little in the last quarter of a century, except here and there in the wards of an enthusiast. Thus, in spite of the fact that modern methods of transport have made the fracture problem more serious than ever it was, and may bring it at any moment literally to the door of any medical man.

A solution, similar in many ways to that suggested by Mr. Hey Groves, was set out by Sir Robert Jones three years ago. It has not found widespread acceptance, though obviously much thought must have been given to the subject. Mr. Hey Groves asks why this is so. "The reasons," he states, "must be of an obscure character, because they have never been put into plain words by those who deprecated any change." The matter is one which we have often discussed with our colleagues when reorganization of the surgical services at our hospital has been under consideration; furthermore, the views of some of those who deprecated such a change were well set out by Gask and other speakers at the discussion at Bath on the subject at the Association Meeting in 1925.

Admittedly such units would provide most efficient treatment for those who came under their care. The vast majority of fractures, however, throughout the country have to depend on treatment by members of the profession who have not had the opportunity of such specialization as work in one of the clinic teams would provide. The problem, so far as the treatment of the majority of fractures is concerned, therefore resolves itself into the question of the education of the average medical man. Would these units provide better teaching for the average student than some less drastic modification of our present methods? We think not. It is suggested that every student should spend two or three months working in the unit. This is good as far as it goes, but it must be remembered that for the majority of practitioners this would, if the system were generally adopted, be all the fracture experience they would get during the period they were students and residents.

Specialization in a teaching school is a double-edged weapon. Whilst it leads to greater efficiency in the few who actually run the department, the student who is taught in it is apt to lose interest in a subject which is labelled "special." Having acquired sufficient gleamings to enable him to pass his examinations he tends thereafter to regard such a subject as one to be dealt with by the "specialist" only. To divorce fracture surgery thus from the work of the greater body of practitioners would be disastrous.

We feel that every large hospital should have a department specially set aside for the treatment of fracture cases. This is a question of administrative efficiency, but we believe it is better to leave the cases in the department under the care of the general surgeons and their corresponding resident officers rather than to bring them under any one surgeon. Applying this method to the hospital in which we work it would mean that the four general surgical units would each have charge of fractures in the fracture department, and that in each unit at least two residents would

each year have that personal responsibility for the care of these cases that alone can educate and fit the practitioner to take charge of such cases after his hospital days are over. Such a department must have attached to it a senior resident or registrar to exercise general supervision, initiate the new house-surgeons into the work of the unit, and be responsible for out-patient fractures attending the clinic.

By a scheme such as this the hospital would have four surgeons and four assistant surgeons who are in daily contact with the fracture problem, and each year new residents would leave the school having had a thorough grounding in the principles and practice of fracture surgery. We do not think it would be an improvement to replace these by a small team of three specialists, working in the rarified atmosphere of a special department, whilst the students of the school passed into the world without the possibility of gaining a working knowledge of fractures after having passed their final examination. We are, etc.,

A PLAN FOR ABOLISHING ARTIFICIAL RESPIRATION FOR WHITE ASPHYXIA OF THE NEWBORN

SIR,—Much observation of the treatment of "white asphyxia" has convinced me that the accepted methods of treatment are on wrong lines, and are more likely to damage than assist the child's chances of recovery.

Let us recall the condition of the "white" baby, and its cause. It arises chiefly as the result of difficult forceps delivery or the too rapid moulding of the head in breech delivery, while sometimes it follows pressure due to abnormally strong pains, and occasionally the child is suffering from pure asphyxia after delivery, produced by premature placental separation or prolapse of the cord. But of all these causes the commonest is pressure on the head by difficult forceps delivery. Is the child really ill because it has been and is being deprived of oxygen? Is it actually suffering from asphyxia? The general appearance of the child is that of simple shock: pallid face, slow feeble heart beat, absent reflexes, toneless muscles, low blood pressure, and rapid cooling of the body are characteristic.

Now Holland, Palmer, Phillips, and others have shown that tears of the septa of the dura mater (chiefly the tentorium cerebelli), with a variable quantity of extravasated blood, are almost a constant feature of the *post mortem* examination. Even after death following breech delivery, where asphyxia is generally recognized as the danger, Holland found that of 16 dead fresh foetuses no fewer than 14 showed intracranial lesions. Tentorial tears and haematomata are gross injuries, and sufficient to cause shock apart from any coincident lack of oxygen.

It is probable that the devitalized baby requires little oxygen for at least fifteen minutes after birth. Those who have seen babies born after "twilight sleep," under the influence of morphine, must have been struck by the way in which the child will lie in its cot, quiet and pale, making little or no effort to breathe, while its pulse beats regularly and strongly, though perhaps slowly. But these babies always recover if labour has been normal. The shallow, infrequent, or absent respirations are an incident of the general state of shock. The child will breathe when the shock has lifted, but artificial expansion of the chest cannot be expected to assist shock. Indeed, can we imagine a worse treatment of shock than the violent movements, massage or squeezing of the chest, abdomen, and loins, which are often observed? During its birth the child has just suffered severe mechanical stress, and only too often artificial respiration is but a continuation of the stress. A further point often forgotten is that firm handling of the loins, often done in Byrd's method of respiration, is liable to damage the suprarenal capsules. At necropsy of the stillborn child this is found to be one of the commonest of all lesions.

In addition to the danger caused by the more violence of the movements of artificial respiration when performed unskillfully, it is an actual hindrance to natural spontaneous inspiration, when the child is making its first effort to breathe. We have all noticed that the early inspirations are made as spasmodic gasps just at the moment when the chest is being pressed upon by the downward movement of the ribs during Sylvester's method. The child tries to expand its chest at the very moment that it is being compressed. But perhaps even worse than Sylvester's or Byrd's method is that of direct mouth-to-mouth insufflation. Here nothing can happen but inflation of the stomach through the oesophagus. The diaphragm is pushed up and the heart still further embarrassed.

The spasmodic inspiratory gasp is of great value to the child, not only by the air intake, but also because of the stimulant action on the pulse, which immediately happens. A finger on the cord feels a great and sudden improvement in the strength of the pulse, coincident with the gasp and lasting for some seconds afterwards. But no such improvement is noticed when the chest movements are imitated artificially.

To sum up, the child is suffering primarily from shock, and not from deprivation of oxygen. Until the shock has passed no treatment is wanted but warmth, the head kept low, blandly dropped into the mouth—not for any reflex stimulation, which is impossible, but because some alcohol may be absorbed by the mucous membrane—and possibly some stimulant hypodermic, such as ether, camomile, or adreline. Professor McIlroy has shown that good results may follow the administration of carbon dioxide, a principle which is the very reverse of artificial respiration.

My contention is that in the aggregate more harm is done by attempting artificial respiration than by its complete abandonment. I believe that most examiners secretly agree with this teaching, but they all feel that their candidates should describe artificial respiration as an indispensable mode of treatment, while all lecturers and teachers equally feel that they must teach it in deference to the requirements of the forthcoming examinations.

Is it not time that the treatment of shock of the newborn should be reconsidered?—I am, etc.,

ALECK BOURNE, M.B., F.R.C.S.

THE DIAGNOSIS OF GASTRITIS

SIR,—The recent interesting correspondence on the relative value of x rays and fractional test meals in the diagnosis of gastritis merits more than passing notice. It raises the question whether practitioners are being led as much as is generally assumed regarding the use of modern methods of precision.

For my own part I agree with Dr Hurst in regarding the use of x rays as of very doubtful value in the diagnosis of gastritis, and in regard to the value of the fractional test meal my experience leads me to precisely the same conclusion. I am satisfied that the more closely we consider the results obtained from fractional test meals in different conditions the more we will be driven to the conclusion that their value has been materially overestimated. The fallacies in drawing deductions from the facts obtained have, it appears to me, received inadequate consideration.

In the past few months I have made an extensive series of observations on the action of a lactic milk preparation in various conditions, clinically accompanied and unaccompanied by disturbances of acid secretion. I have used as controls the ordinary gruel meal and sweet milk. The results of these observations confirm a part of Dr Molloy's conclusions, they also appear to show clearly that in his presentation of the subject Dr Hurst fails to cover the whole field of the problem. It must not be assumed that I do not believe in the value of the fractional test meal, but my experience leads me to enter what I believe to be a necessary word of caution as to the readiness with which current teaching is accepted as a reliable practical guide in diagnosis and treatment.—I am, etc.,

CHALMERS WATSON, M.D.

¹ Holland. Report on the Causation of Foetal Death. Ministry of Health Report No. 7.

PAPULAR URTICARIA

SIR,—In his reply to my letter Dr Hallam (December 8th, p 1065) brings forward as additional evidence that papular urticaria is not influenced by dieting the fact that of 52 cases reported in the *British Journal of Dermatology* (March, 1927) 10 were in infants who were being breast-fed, and that weaning did not ameliorate the condition. But in the original paper Dr Hallam states apropos of these cases, "a child may become sensitized to a protein through its mother's milk," and quotes literature in support of this. Later in this paper he quotes the work of Sidlick and Knowles, who found that certain of their cases were cured on a restricted diet.

I do not wish in any way to disparage Dr Hallam's very valuable contributions to our knowledge of this disease, but I think he is going too far when he denies, as he now does, that foodstuffs can play any part in its production.—I am, etc,

Clifton Bristol Dec 8th NORMAN BURGESS, M A, M B,
MRCP

SIR,—The various forms of urticaria are due to a great variety of causes, many of which, in my opinion, are foods.

One of the worst cases I have ever seen was that of a lady who had eaten some mussels during luncheon at one of the large hotels. Other more chronic cases may be due to eating eggs, fish, or Brazil nuts. One of my patients, sensitive to apples, would develop urticaria if she stayed any length of time in an apple orchard. If she peeled an apple her hands would swell from the external contact with the fruit, this has also been noted many times in handling eggs and eggshells. Unfortunately the skin reactions are not so valuable or certain in these cases as they are in asthma. Schloss demonstrated this fact many years ago. A child could sometimes take an egg with impunity, and at other times the ingestion of an egg would cause urticaria. Schloss found that on these occasions the child would respond with an urticarial wheal to the application of egg as a dermal test, but not at other times. A patient of mine gave a reaction to all the legumens, and the urticaria disappeared entirely when these were avoided. Other patients are sensitive to animal hairs and feathers, which can be demonstrated with the skin reactions.

I was not aware that patients lost their urticaria so commonly on entering hospital. Many of the asthmatics gain the same freedom. I have always attributed this to leaving the cat, dog, feather-bed, or other proteins at home, and I have proved it in numbers of cases. I would suggest that if Dr Hallam wishes to make further investigations it might be worth his while to test the patient's reactions to a wider circle of proteins, possibly including a sample of dust from the patient's house. The full value of the dermal reactions has never been credited to them, nor is it likely to be, while some of the proteins on the market are so singularly inefficient.

In closing this letter and thanking Dr Hallam for his paper, may I also congratulate Drs Barber and Ortel on their biochemical investigations into these allergic phenomena?—I am, etc,

FRANK COKE

PROBLEMS IN GASTRIC SURGERY

SIR,—With reference to the article by Sir Berkeley Moynihan in your issue of December 8th (p 1021), which appears to be a collection of very contradictory statements, am I to understand that he accuses me of "faking" my x-ray results? It may be of interest to him to know that no case in which I have diagnosed a gastric ulcer that has come to operation has shown no ulcer present. In a few cases I have missed small ulcers which were present, and I lay no claim to infallibility, but I have yet to diagnose an ulcer which is not present.

With reference to the preparation of the stomach for the opaque meal examination, will Sir Berkeley, of his experience of x-ray examinations, state what he would recommend to be carried out? Of my own small experience, at the rate of some 1500 examinations a year in a big hospital department extending over seven years, I have found that the best results are obtained by examining the stomach at

the earliest possible moment, when empty, and before any palliative measures have been adopted.

Finally, I can assure Sir Berkeley Moynihan that quite a large number of apparently large ulcer craters do disappear, from an x-ray view, in the time stated. Perhaps if he will read Dr Barclay's interesting contribution in the same issue it may dawn on him why this is quite possible.—I am, etc,

DNRE

ACHALASIA OF THE CARDIA SO-CALLED
CARDIOSPASM

SIR,—From a paper published in your issue of November 24th (p 932) it appears that Mr H H Greenwood, having operated last April upon a single case of so-called cardiospasm which has not yet relapsed, feels that he is in a position to regard my views as "inadmissible," though they are based on prolonged clinical investigation on at least twenty-five cases, supported by the pathological work of Mr G W Rake on nine specimens, as well as the clinical and pathological observations of many other observers. He is good enough to add that my views have "gained a certain amount of credence by a parrot-like repetition, unsupported by facts." He then makes the amazing assertion that the inflammation and degeneration of Auerbach's plexus found by Rake, and more recently by Cameron of Glasgow and Mosher of Boston, in every one of some fifteen specimens, can have nothing to do with the pathogenesis of the disease.

The relief following Walton's operation is of exactly the same nature as that following the use of Plummer's bag or the mercury tube, and is simply due to stretching, the effect of which is to produce a more favourable postural tone of the sphincter, as anyone familiar with Sherrington's work would realize. There is no question of curing this condition by any form of treatment. All that can be done is to reduce the resistance offered by the sphincter, as the changes in Auerbach's plexus are of a permanent character, the hypertrophy and dilatation of the oesophagus remaining unaltered, though the stagnation may be completely overcome.

If Mr Greenwood has the opportunity of examining a second case, he might find it interesting to pass a mercury tube before resorting to operation. He will discover that it meets with no resistance, and is not gripped when it passes the cardia, in marked contrast with the firm resistance felt by the finger and the grip exerted upon it by the anal sphincter in the presence of spasm.

Mr Greenwood would have been wise to visit a pathological museum or consult the extensive literature on the morbid anatomy of the condition before publishing his statement that the existence of hypertrophy of the muscular coat of the oesophagus remains a subject of contention. Obvious hypertrophy, quite as great as that of the colon in Hirschsprung's disease, is always present. Mr Greenwood states that the term "achalasia" implies a pathology similar to Hirschsprung's disease and hypertrophic stenosis of the pylorus; it is not my fault if the word has this peculiar effect upon him. Achalasia means absence of relaxation; the word was first applied by me in 1914 to the cardiac sphincter in cases of hypertrophied and dilated oesophagus. It was not until 1919 that I suggested that Hirschsprung's disease had a similar pathology, entirely distinct from that of hypertrophic stenosis of the pylorus, in which the hypertrophy of the sphincter is in striking contrast with the normal size or even atrophy of the cardiac and anal sphincters in other conditions. Hirschsprung's disease is probably acquired in early childhood, and is not congenital, and many cases of achalasia of the cardia have been observed in young children, there is nothing unusual in the age of onset in Mr Greenwood's case.

I shall still recommend the mercury tube with confidence, in spite of Mr Greenwood and his one "cure." Almost all patients are greatly relieved by its use, and the majority, after a varying period, are able to dispense with it entirely or only pass it at long intervals. The most difficult cases I have met with are those which have been treated by the

foreable dilatation used by Mr Greenwood, as this may lead to the gradual development of a fibrous stricture, the dilatation of which is painful, this is hardly surprising, as the violent pain felt by Mr Greenwood's patient for twenty-four hours after the operation shows how the tissues must have been damaged, in contrast with the slow and painless dilatation produced by a series of mercury tubes. A number of deaths have occurred after the use both of Plummer's bag and of foreable dilatation, but the mercury tube is entirely free from danger.

Before criticizing my "ingenious statements" Mr Greenwood should make an attempt to understand what he criticizes. It is easy to demonstrate that the oesophagus in this condition is permanently filled with a mixture of food and fluid, which forms a column about eight inches high. When food is eaten the resistance of the closed sphincter is overcome by the weight of the column, and its opening allows the excess to pass, it closes once more directly the column is again only eight inches high. The mercury tube acts solely by its weight, exactly like the column of food, but its weight is constant, whereas that of the column of food falls as its length diminishes, and one of less than eight inches is insufficiently heavy to keep the sphincter open.

Mr Greenwood finishes his paper with the conclusion that because the patient bolted his meals this must be 'the main factor responsible in all cases,' and yet he has the courage to write that it is "pure theory and extremely improbable" that the constant changes in Auerbach's plexus demonstrated by Rake have anything to do with the development of the disease!—I am, etc.,

New Lodge Clinic Windsor Forest Dec 1st ARTHUR F. HENST

Sir,—Mr H. H. Greenwood, in discussing the condition of achalasia, makes certain statements on the pathology of this condition which cannot pass unchallenged. He asserts that the term "achalasia" implies a condition analogous to that of congenital hypertrophic pyloric stenosis. Whatever views may formerly have been held on this point, there can be no doubt now that this condition is in no sense one of achalasia (absence of relaxation). The spasm is obvious clinically, there is hypertrophy of the sphincter such as is not observed in achalasia, and, finally, the nerve plexus is intact.

Passing now to cardiospasm itself, Mr Greenwood states that 'hypertrophy of the muscle forms no essential feature of cardiospasm.' But such a statement is entirely contrary to figures obtained from necropsy records, and perhaps I may be allowed to quote three of my own cases. The first was one of the early stage of the disease before secondary dilatation had occurred. In this case the measurements were

Just below the cricoid	4.0 cm
Middle of oesophagus	1.8 cm
Just above the cardia	2.4 cm

The cardiac sphincter was not hypertrophied. In a series of twenty normal oesophagi examined, the average for these measurements has been

Just below the cricoid	0.13 cm
Middle of oesophagus	0.25 cm
At the cardiac sphincter	0.3 cm

In two cases of typical long-standing achalasia (as yet unpublished), in spite of marked dilatation, the figures were

	CASE I	CASE II
Just below the cricoid	0.3 cm	0.4 cm
Middle of oesophagus	0.6 cm	0.8 cm
At the cardiac sphincter	0.3 cm	0.3 cm

(All these figures refer to total thickness of the wall.)

These are only three examples from a series of nine, all of which show similar findings. Comment is scarcely needed on these figures.

In Mr Greenwood's case spasm of the cardia was actually demonstrated at operation. He therefore claims, from this "pathology of the living," that spasm is a constant feature in the disease. It may, however, be pointed out that the findings with the mercury bougie are just as much the "pathology of the living" as are those findings with the

fingers, and it is the experience of the majority of users of the mercury bougie that there is no spasm commonly present at the cardia, this being shown by the absence of gripping of the instrument in any degree, by the sphincter. Recently I have pointed out that, until destruction of the plexus is complete, any oesophagitis or irritative lesion may be sufficient to excite the neurons to such an extent as to produce a spasm of the cardia, which is, however, in the majority of cases, only of short duration.

The points that Mr Greenwood raises about Auerbach's plexus are difficult to understand. He admits, apparently, that a destructive lesion may and does exist. He then proceeds to state that the presence of such a lesion is not germane to the question of cause. What, then, is his standpoint? Either that the lesion is not a primary one, or that a primary destruction of Auerbach's plexus will in no way affect the nervous mechanism at the cardia.

The first of these objections may be disposed of by reference to the first case quoted in this letter. It has been objected that the lesions in the plexus are secondary to the oesophagitis present in the chronic cases, but in this case there was no macroscopical or microscopical sign of any oesophagitis, and yet the lesion in the plexus was already advanced.

The second objection is even more easily dealt with. All physiological work, recent and remote, macroscopical and microscopical, has been to show that the vagus, stimulation of which relaxes the cardiac sphincter and causes contraction of the rest of the circular muscle of the oesophagus, has a cell station in Auerbach's plexus—that, in fact, all the ganglion cells in Auerbach's plexus are neurones on the vagal path. Destruction of these cells, such as Mr Greenwood apparently admits to occur, must then produce an absence of relaxation of the cardiac sphincter, and, occurring in man, produce the condition of achalasia—so-called cardiospasm. Kronecker and Meltzer over fifty years ago produced in rabbits, by division of the vagi, a condition exactly similar to achalasia in man.

The postulate that destruction of the plexus can occur without upset of function is thus clearly untenable. The action of the mercury bougie or any other form of dilatation of the sphincter is purely mechanical, and, in spite of Mr Greenwood's statement, its success in no way suggests an immediate recovery of the nerve lesions—I am, etc.,

GUY'S HOSPITAL S.E.1 Dec 4th

G. W. RAKE

SIMPLE PHLEBITIS AND EMBOLISM

Sir,—In the *British Medical Journal* of December 1st (p. 1010) Dr O. Hilton asks for the experience of others in cases of simple phlebitis. In upwards of forty-five years of active general practice I have seen many cases, but have never ventured outside the orthodox procedure of strict bed. The only instance of death I have encountered was in the case of a working woman. When I saw her she had marked phlebitis and much pain in the leg below the knee. This had been going on for some days, during which she had continued to carry out her household duties. I insisted on her going to bed at once. The next morning at 7 o'clock I was called to see her. Her husband informed me that she sat up in bed on waking and was talking to him, when she suddenly fell back dead. I have often quoted this case to patients who have been unwilling to carry out instructions—I am, etc.,

Lechlade Dec. 5th

GEORGE DE J. PATTERSON

Sir,—I have read with great interest Dr O. Hilton's letter. It has always seemed to me that the danger of thrombi of phlebitis getting loose and forming emboli has been much exaggerated. I am convinced that in a number of cases of traumatism, such deep-seated phlebitis with thrombi does arise, but is not diagnosed, and the cases improve with massage and mobilization. Moreover, I consider that, in the early stages of phlebitis, thrombi do not necessarily arise at all, or else at a much later date than is usually supposed. I have during the last thirty years treated a large number of cases of fresh phlebitis by means

¹ Reported in *Guy's Hospital Reports* vol 76 1926 p 145

of manual vibrations applied once daily (in some cases twice daily), and have in practically every case had rapid and permanent results—I am, etc.,

London W 1 Dec 6th

EDGAR CYRIAC

SIR—I am much interested in Dr Hilton's letter on this subject, on which I can speak from first-hand knowledge having had one or more attacks of phlebitis every year since 1917, when I contracted it in the army.

During my first attack I was treated with belladonna applications and by being kept strictly in bed in a military hospital in England. I was visited daily by an eminent, though aged, physician in uniform who felt my leg each day, and remarked that while the thrombus was there I must on no account get out of bed. After nearly two months the thrombus could no longer be felt and I was allowed out of bed and eventually, after a month's convalescence, back to duty. I had another attack in 1918, while still in the army, but managed to get out of bed after three weeks. When, however, after the war, I returned to practice, and had one or two attacks each year, three weeks was much too valuable to spend in bed, and I managed to convince myself that there was little or no risk of the thrombus becoming detached. During the last few attacks I have had (the last was in May of this year) I have gone to bed at once on the appearance of signs of phlebitis, and have had cold water applications to my leg (I have tried antiphlogistine, but thought cold applications better). Internally I take—as I do when threatened with an attack—ten minims twice daily in water of the French preparation, extract of horse chestnut (*solution d'extra de marron d'Inde*), which I am convinced has a beneficial effect on at least the pain, three or four friends to whom I have recommended it agree on this point. When the pain goes, as it does usually in three or four days, sometimes a week, I get up and about again, at first with the aid of a stick, and apply a simple ointment, such as zinc, to the affected part. I twice applied an iodine ointment, but it seemed to make the phlebitis worse.

Colleagues who have met me limping in the street have often expressed themselves as horrified when I have said that the temporary limp was due to phlebitis, and have tried to persuade me back to bed. But I remain unconvinced that I am much more likely to have an embolism than any of the hundreds of persons whose varicose veins have been injected with sclerosing solutions. I would have tried this injection treatment, but I am told that my deep veins have been affected as well as my superficial ones. I may yet fall back on the "cure" at Bagnoles de l'Orne in Normandy, though I have been told that it is the duller spa in Europe and an eminent surgeon has tried to persuade me to have a course of injections of a *Staphylococcus albus* vaccine, on the ground that the phlebitis is caused by a low infection from the skin, but I have not done so. I still think that a few days in bed at the beginning of an attack, until the pain is gone, is all that is necessary—I am, etc.,

London W Dec 3rd.

THE SO CALLED TITANIUM RAYS

SIR,—Dr C B Heald's letter in the *British Medical Journal* of November 24th (p 962) was most opportune. Dr A Roberts's reply in your issue of December 8th (p 1067) is most unconvincing. I would be greatly obliged if Dr Roberts would give me precise information on the following points: (1) Where and from whom he obtained his "electrodes containing titanium" in 1924. (2) When and where he first stated that titanium was only present in the electrodes to the extent of 1 to 5 per cent. (3) What is the actual price per inch Dr Roberts pays for his "electrodes containing titanium" and from whom does he obtain them?

Dr Roberts's experiment with the cowhide is really too ingenious. Apparently he is not aware that an arc between two "electrodes containing titanium," or in fact any arc, gives off visible light, and that the red rays especially have considerable powers of penetrating animal skin, and would therefore naturally affect the photographic plate. Many physiotherapists will be surprised at Dr Roberts's ignorance of the physical properties of ultra-violet rays. This all demonstrates the urgent need that exists at the present time for drastically purging physiotherapy of all the nonsense which is, alas! only too prevalent—I am, etc.,

W KERR RUSSELL, M D

SPONTANEOUS PNEUMOTHORAX SUPERIMPOSED ON ARTIFICIAL PNEUMOTHORAX

SIR,—In your issue of December 1st (p 1011) Dr Hugh Garland comments on the case of lung rupture recorded by Dr S P Wilson in the *Journal* of November 17th. Dr Garland suggests that the "staircase" temperature chart in the series of similar complications recorded by Blair and myself might be due to infection of the pleura.

In his memorandum Dr Wilson states that air was removed from the pleura after the rupture had occurred, and that the temperature was normal on the following day. In the only case (W F) of our series where removal of air was indicated we noted that the temperature dropped 1 degree and four degrees respectively (lung rupture occurring on two occasions in the same patient) and returned to the level obtaining before the rupture occurred. It would seem to be quite possible that the same sequence of events occurred in Dr Wilson's case, as no mention is made of the temperature at the time of rupture, the previous level of temperature in his case being fortunately normal.

Exactly parallel "staircase" charts occur in spontaneous pneumothorax arising in patients untreated by collapse therapy, such patients recover from the immediate effects of the pneumothorax and show no evidence of violently infected pleura. In fact, when the chart assumes this character in the first three days a good prognosis can usually be given.

Since the publication of the paper referred to by Dr Garland, further observations would seem to suggest that the rise of temperature is not solely due to increased intrapleural pressure but to the effect of sudden mediastinal displacement. In Dr Wilson's case the occurrence of a lung rupture might lead to no such displacement owing to the splinting effect of an air and fluid in the unaffected pleura.

Barlow and Thompson state that small pneumothoraces are extremely common in pulmonary tuberculosis. I have only noted three of this type. They were all on the left side, the diagnosis resting on a sudden rise of temperature and an immediate slight shift of the apex bent or mediastinum. In one case of traumatic lung rupture following an attempt to induce an artificial pneumothorax the temperature, previously above normal, fell to normal limits. X rays showed a shallow collapse of the peripheral parts of the lung, the central area being consolidated, no mediastinal displacement was observed—I am, etc.,

Worthing Dec 2nd

DEFINITION OF DRUNKENNESS

SIR—Dr L Rowland Fothergill writes in your issue of December 1st (p 1010) that I stated on November 24th (p 964) that the British Medical Association Committee's definition of drunkenness was specially drafted to apply to the offence of being drunk in charge of a motor vehicle. I said that it appeared to have been so drafted, and I still think it does. He says it was intended to apply to accidents in factories or other employments, to walking on a cliff or other height, to conducting a child through or near traffic. I am unable to find any of these things scheduled as a statutory offence. What I do find, and I said so in the same letter, is that there are statutory offences in which no element of danger is involved. Possibly, under the B M A Committee's definition, it may be advanced that a man drunk on licensed premises is so much under the influence of alcohol as to render him unable to execute safely the occupation on which he was engaged at the material time, and so, liable to spill his beer—I am, etc.,

Thurstone Sheffield Dec 2nd

Gordon Wilson

THE THOMAS SPLINT

SIR,—Professor Ernest Hey Groves, President of the British Orthopaedic Association, in his address on the treatment of fractures, printed in the *British Medical Journal* of December 1st (p 993), asks why the Thomas splint is not used when fracture cases have to be transported over country roads. May I say that the Home Service Ambulance Committee has done its best to ensure the use of this splint by equipping 130 of its ambulances with it. These ambulances are in use in rural areas, and

are in charge of members of the Order of St John and the British Red Cross Society whose training includes the application of the Thomas splint—I am, etc.,

ETHYL CHLORIDE ANAESTHESIA IN TONSIL AND ADENOID OPERATIONS

SIR,—There is one point that has not been referred to, so far as I have seen, in the correspondence on the subject of ethyl chloride as an anaesthetic for tonsil and adenoid operation, and that is the comparatively long analgesic period which succeeds the anaesthetic one. The former is sufficiently long to allow of examination of the tonsil bed and the removal of any fragment of tonsil in the few cases where the whole has not been removed. It is likewise sufficiently long to insert a stitch in the pillars or tie a bleeding point in the still rarer cases in which it is advisable to do so after tonsillectomy in children.

After a prolonged and extensive experience of ethyl chloride, dating from a few years after its introduction, I regard it as a most satisfactory anaesthetic for the guillotine enucleation of tonsils in children. It is efficient, safe in experienced hands, and is followed by little or no shock. The cases, however, in which ethyl chloride is to be used should be carefully chosen. It may, on the one hand, be a suitable anaesthetic for an adult tonsillectomy where the tonsil is not buried or adherent, while on the other hand it may be unsuitable for enucleation in a child where the tonsils are buried, adherent, and have been the site of frequent attacks of tonsillitis. The rapidity of induction of and recovery from anaesthesia with ethyl chloride make it most valuable where large numbers of children have to be dealt with, though speed alone should not be a main consideration. It is also, usually, a safer anaesthetic than chloroform or ether in those institutions where, unfortunately, children are not detained as in-patients after operation.

As to the question of haemorrhage, a great deal too much stress is laid on the loss of a little blood in these cases. In many there is not only a septic tonsil, but a septic bed, and it is an advantage that the part should have a little flushing, it is a mistake, speaking generally, to seek to tie every bleeding point or stitch up delicate structures like the faucial pillars after an operation to deal with a septic condition. It is sometimes contended that the oft-quoted "general surgical principles" are not carried out if there is any bleeding from a tonsil that is not stopped, but surely in every surgical operation a certain amount of capillary bleeding is left to look after itself or stopped by pressure of dressings and bandages. In enucleation of the prostate, which has some resemblance to that of the tonsil, nature is trusted to some extent. Bleeding is, of course, occasionally met with from an exceptionally large or rigid vessel, the walls of which have not been twisted and frayed as is usual in this method of operation, but, as already stated, this can be dealt with under ethyl chloride anaesthesia. Nor is it necessary to break the rule that it is wiser for the patient not to leave the table till haemorrhage is controlled, as in the average case a little gauze pressure will do so. It is always wise to reopen the gag, apply this pressure, and then do any toilet that may be required in the exceptional case.

The operation should usually, in my opinion, be a little more elaborate, though not much more tedious, than that described in the original paper. In most cases it is of advantage to use a strong tonsil forceps passed through the guillotine to pull the tonsil from its bed and, when necessary, to dissect it out partially, except in cases where the tonsil is very prominent and has a shallow bed. The forceps and dissector made for me by Messrs Mayer and Phelps, or Waugh's forceps, will be found useful for this purpose. The tonsil having been thus freed, the blunt guillotine is pressed home and enucleation completed by that instrument, which gives a better healing surface than a complete dissection.

One of your correspondents has stated that the best anaesthetic is a good anaesthetist, and there is a great deal of truth in this statement, it will make ethyl chloride

anaesthesia all the more satisfactory when the administrator is an expert. Another correspondent seems to think that the practitioner sees the bad results of tonsil and adenoid operation, and the specialist does not know the after history of the patient. His experience must surely be unusual—namely, that the effects of the operation are bad and not good, and that the cases are not seen after operation. Personally, I always like to see the patient in a month, whether hospital or private, and have usually been impressed with the great improvement in the general condition—I am, etc.,

Bath Dec 1st

H. NORMAN BARRETT

SIZE OF TYPE

SIR,—I should like to obtain the views of the readers of the *British Medical Journal* on the question of the size of the type used in the printing of our paper. I regard it as far too small and as causing considerable eyestrain in those who read it. In the issue of December 1st there are twenty-six columns of this particular variety to which I object. It is, I believe, technically called "minion." In elementary school books it would not be allowed, and I protest against its use in our *Journal*. We would much rather have a little less matter printed in a decent readable type than be compelled, as we are at present, either to strain our eyes unduly or to omit reading the part of the *Journal* printed in microscopic characters—I am, etc.,

Here Dec 2nd

L. A. PARRY

* Dr PARRY raises a difficult question which has long exercised the minds of those responsible for the conduct of the *Journal*. Far more material is received every week for publication than can be printed in the space available, and the use of small type in Parliamentary Notes and elsewhere helps us to meet the very varied tastes of 34,500 members within the limits of a single issue. We shall be glad to receive the views of readers, and to communicate them to the *Journal* Committee.

ALKALI THERAPY

SIR,—My attention has been called to a somewhat serious error in Dr A. T. Hurst's paper in the *British Medical Journal*, November 3rd, 1928 (p. 780, column 2), concerning the descriptions of "alcol" and "neutralon." This error also occurs in the paper "Contribution to the study of 'alkalis' as therapeutic agents," by Freezer, Gibson, and Matthews, published in the *Guy's Hospital Reports*, 1928 (p. 192).

Confusion has arisen in the description of the above two materials. "Neutralon" is aluminium silicate and "alcol" is colloidal aluminium hydroxide. These two materials were mentioned in the above paper, and the latter was found by Mr Matthews to contain 55 per cent of aluminium hydroxide. It is most unfortunate that the descriptions were reversed in the paper, and an apology is due to Messrs C. A. F. Kahlbaum of Berlin, the proprietors of "neutralon," and to Messrs A. Wander, Ltd., of London, the proprietors of "alcol."

The results given by Freezer, Gibson, and Matthews are those of physico-chemical measurements, and they are quoted as pH values of a solution of hydrochloric acid which before treatment with "alkali" has a pH value of 1.0. The relatively low efficiency of "alcol" as a neutralizing agent, as found by the above authors, is in keeping with the statement of Messrs Wander, Ltd., that "alcol" fixes the acid not by neutralization but by adsorption—I am, etc.,

Guy's Hospital Medical School
London SE1 Dec 5th

C. S. GIBSON

A CLINICAL NOTEBOOK OF 1710

SIR,—In Mr Murrehead Little's note, published under this heading (December 8th, p. 1052), he stresses, among the names of the various wards, "the strange one of Cutting" which was common to the two (then only existing) London hospitals of St Bartholomew and St Thomas. This is explained by Sir D'Arcy Power as being the operation ward at St Bartholomew's. At

St George's, and the other early voluntary hospitals, cutting for the stone was performed in one ward allocated to that purpose, that being known as the "cutting" ward. There was then no operating theatre, operations being performed either in the surgery or in the ward where the patient lay—I am, etc.,

G C PACHEA

Obituary

MICHAEL MARTIN DAVITT, M B, B Ch, B A O,

Visiting Physician and Superintendent Galway Central Hospital,
Lecturer in Clinical Medicine, University College Galway

We regret to announce the death of Dr Michael Davitt, which occurred at his home in Galway on December 1st. The news of his death, which was altogether unexpected, caused widespread sorrow in that city, where he enjoyed the esteem and friendship of all classes. On November 30th, when proceeding to lecture at University College, he was taken ill with a pain in the back of the neck, which was quickly followed by the more pronounced symptoms of tetanus. He had had a severe attack of this disease two years ago, following an accident, while lifting his little son over a wall, he scratched his chest on a rough and dirty stone.

Michael Martin Davitt was the eldest of the three sons of the late Michael Davitt, and was born at Ballybrack, co. Dublin, on May 23rd, 1890. Educated at the Christian Brothers', Dublin, and Dun Laoghaire, he subsequently went to Blackrock College, twice visiting California with his parents and receiving part of his earlier education there. He graduated B A and B Sc (with honours) at the National University of Ireland in 1911, and three years later headed the first honours list of graduates in medicine, surgery, and obstetrics. After serving as house-surgeon and house-physician in the Mater Misericordiae Hospital, Dublin, he practised for some time in England, and was attached to the Mile End Infirmary. On his return to Dublin he became assistant physician to the Children's Hospital, and visiting physician to Jervis Street Hospital. Eight years ago, on the establishment of the Central Hospital, Galway, he was appointed visiting physician and superintendent of that institution, being also lecturer in clinical medicine at University College, Galway. As a student he was elected to the first governing body of this institution, under its new charter, by the votes of the graduates.

Dr Davitt took a keen interest in outdoor sports, and played forward for many years under the Rugby code. At the time of his death he was president of the Connaught branch of the Rugby Football Union. He was an enthusiastic lover of music, and was prominent in the organization of the coming Schubert centenary festival in Galway. While not an active politician he was a supporter of the existing Free State Government, by whom he was nominated as a candidate for the recent election to the Senate. Deep sympathy is felt for his mother, his sister, and his two brothers—Judge Cahill Davitt, and Dr A F Davitt, of Jervis Street Hospital, Dublin.

We regret to announce the death of Dr WILLIAM BROWN HUNTER, one of the oldest and best known medical practitioners in the North of Ireland, which occurred at Londonderry on October 22nd. Born of farming stock in county Derry, he received his early education at Londonderry, undertaking his professional studies at the University of Edinburgh, where he graduated M B, C M in 1866, proceeding M D three years later. He commenced practice in Scotland, at Yetholm and Jedburgh, and subsequently removed to Lly, afterwards returning, about forty years ago, to his native country, where he soon established an extensive general practice in Londonderry. He had, however, a specialized interest in diseases of the eye, ear, and throat and, in conjunction with the late Dr Donaldson he inaugurated a campaign designed to secure more adequate facilities for their treatment. The result

of this effort was the institution of the Londonderry Eye, Ear, and Throat Hospital, which has a long history of useful service, and which meets the needs of patients from a wide area in the North-West of Ireland. Dr Hunter was for many years honorary surgeon to the hospital, and even after his retirement some years ago continued to display great interest in its working. His ungrudging service to the community, his professional skill, and his kindness and sincerity gained him the respect and affection alike of his colleagues and of the public, and his death has caused general regret. He took a prominent part in the affairs of his profession, and as a member of the British Medical Association held office in one capacity or another almost continuously for over thirty years. In the old Londonderry and North-West of Ireland Branch he became a member of the council in 1893, and was later honorary treasurer and afterwards vice-president of the Ulster Branch, in the Derry Division he served as chairman in 1906, and was a member of the executive committee from 1904 until three years ago. Dr Hunter had been a widower for fifty years, his wife having died soon after their marriage.

Dr JOHN McASKILL HENDERSON, who died at Nairobi, Kenya, on November 22nd, at the age of 33, had for the past two years been engaged in research work in that colony. A native of Ayrshire, he received his medical education at the University of Edinburgh, graduating M B, Ch B in 1922, he was also a graduate in arts and science. In 1926 he became D Sc Aberdeen. After serving for a brief period as assistant physician at the Royal Edinburgh Mental Hospital, and spending a year in general practice in Glasgow, he joined the physiology department of the Rowett Research Institute in Aberdeen. About two years ago he spent some time at Cambridge, and afterwards proceeded to Kenya to undertake research on nutrition at the instance of the Medical Research Council. He was a member of the British Medical Association. A colleague writes: "The death of John Henderson at the age of 33 will touch the hearts of many teachers and fellow students who knew him at the Universities of Edinburgh, Aberdeen, and Cambridge. From Ayr Academy he passed with many honours to Edinburgh, where, as the editor of *The Student* who set a new standard of criticism and humour, as one who counted the company of men and yet found time to head the class lists, and as the ready helper of perplexed freshers, he will be remembered by many of his fellows. At the Rowett Institute his constant application, imagination, and independent judgement were soon recognized by the director and his colleagues, who saw that Henderson's work combined a rare sincerity and high technical skill. In Kenya, in the course of his work on nutrition, he investigated the diet of natives in hospitals, prisons, and homes, and a high authority has described this work as of "high practical value and permanent importance," and predicted "a brilliant future"—but his fatal illness had already begun. Science has lost a devoted follower, and those who knew and loved him best have lost a sensitive friend whose nature was ever buoyant with an undercurrent of quiet playfulness—a man interested in life first and in science as a part of life."

Dr MONTY BARANOV, whose recent death is mourned by his many friends in England and South Africa, was born at Vryheid in 1895, and received his early education at King Edward the Seventh School, matriculating in 1912. He came to England in 1913, and joined University College, London, as a medical student in that year. He showed great aptitude for the medical sciences, and was a prosector in anatomy at the Royal College of Surgeons, London, in 1915 and 1916. He obtained the M R C S and L R C P diplomas in 1918, and was appointed house-physician to Dr C. Bolton at University College Hospital. He graduated M B, B S Lond. later in that year, and went to France with a commission in the R A M C. He proceeded M D in 1920 while casualty officer at this hospital, and, having developed a keen leaning towards ophthalmology, he also assisted Mr Percy Fleming and Sir John Parsons. He then entered the Royal London Ophthalmic Hospital

(Moorfields-) and rose to the position of senior house surgeon. Later he became chief clinical assistant at Moorfields, and obtained the D.O.M.S. in 1923. Towards the end of that year he returned to his home in Johannesburg, taking with him many good wishes from his chiefs and associates in London. He then commenced consulting ophthalmic work in Johannesburg, and in 1924 was elected honorary assistant ophthalmic surgeon to the Johannesburg General Hospital. He continued actively at work until some six weeks before his death. A colleague writes: Baranov was not only popular with the honorary and nursing staffs of the Moorfields Hospital, and his popularity followed him to South Africa, where he earned the respect and esteem of all who were associated with him in his work. He took a keen interest in his non-European work, in which his fine operative ability soon made itself manifest. Baranov was full of the joy of life in work and at leisure. He had in the highest degree zest and energy for doing things, care for his patients, and love for his fellows. His keen sense of honour, together with his reliability and brilliance, secured for him a position of great trust and the admiration of his colleagues. His sympathy, understanding, and generosity gained him the sincere affection of many friends. The deepest sympathy is felt for his young widow and his mother and father.

Dr JOHN MACGREGOR, who died on November 27th at Iytham St. Annes, Lancashire, was a well known figure in medical circles in various parts of the country, and had been for over thirty years honorary physician to the Newspaper Press Fund, an office in which he succeeded Sir Benjamin Richardson. He received his medical education in Edinburgh and at the London Hospital, obtaining the diplomas L.R.C.S., L.R.C.P. Edin. in 1884, and being admitted to the Membership of the Royal College of Surgeons of England a year later. Earlier in his career he was a demonstrator in anatomy in the Edinburgh School of Medicine, and he was afterwards pathologist and ophthalmic assistant in the Royal Infirmary. Subsequently he was engaged for a period in private practice in Yorkshire, and ultimately established himself as a consultant in London, where he built up a large practice. During the war he rendered valuable service in the medical examination of recruits, and later in furnishing medical aid during air raids. In addition to his work for the Newspaper Press Fund, he gave a similar service to the Press Club, of which he was an honorary member. He was a Fellow of the Royal Medical and Physical Societies of Edinburgh. Dr MacGregor is survived by his widow, who is well known for her philanthropic and social welfare work in Leeds and London.

Dr SIDNEY JAMES CLEGG, who died on November 23rd, received his medical education at the University of Manchester where he graduated M.B., Ch.B. in 1909, and proceeded M.D. in 1914, he obtained the D.P.H. in 1910. After holding the post of resident medical officer at the Infectious Diseases Hospital, Newcastle-on-Tyne, he was appointed deputy M.O.H. At the outbreak of war he became medical officer to a battalion, and subsequently organized and commanded one of the first sanitary sections. At the end of the war he held the rank of D.A.D.M.S., and was awarded the O.B.E. (Military) and the Médaille d'Honneur des Epidémies (on argent). He won especial distinction for services in connexion with the introduction of methods for the disposal of refuse and also the control of milk. At the end of the war he returned to Newcastle, but, in 1923, was appointed medical officer of health for Durban, Natal, where he remained for five years. His health suffered in consequence of the exigencies of his work and also of the climate, and he returned to England last September, making his home at Rhos-on-Sea. A colleague writes: Clegg's passing removes a striking figure from preventive medicine. His wide sympathies and broad outlook endeared him to all with whom he came in contact, and created for him a very large number of friends.

Medico-Legal

A SPECIALIST'S FEES

WHEN a specialist sued for fees in the King's Bench Division on December 5th, Mr Justice McCardie said that the difficulties would not have arisen if doctors could tell their patients in clear terms at the beginning of the treatment the scale of fees they intended to charge. His Lordship thereupon gave judgment for Dr J. H. Douglas Webster, a specialist in radiology and electrical treatment, and honorary physician in charge of the radiology department at the Middlesex Hospital, for fees claimed for treatment of Miss Muriel Clifford of Bloomsbury Square, London, for severe sciatica, with the exception of a special fee of £30 for a journey he made at the defendant's request from Eastbourne, where he was then staying, to give her treatment in London. Dr Webster's counsel said that this fee was really smaller than he could have reasonably charged, for it was a custom of the medical profession that a specialist who went out of town to a patient was entitled to charge one guinea a mile for the distance travelled, and this custom equally applied to a specialist who was staying at Eastbourne making a journey to London at his patient's request.

Mr Justice McCardie recognized the importance of maintaining an adequate remuneration for the medical profession, for it required seven or eight years and the spending of thousands of pounds for a doctor to become qualified. He had to take expensive rooms, and he must maintain an adequate social standing. Therefore it was impossible to regard the medical profession as other than one entitled to adequate remuneration. His Lordship held that Dr Webster's charges were reasonable, except for the fee for the Eastbourne journey, which he reduced to £4.

The Services

ARMY MEDICAL ADVISORY BOARD

It has been decided to reconstitute the Army Medical Advisory Board with the following terms of reference. To advise the Secretary of State for War on any question of policy in connexion with the Army Medical Service, on which he may desire to consult them. The Board will consist of the Director-General A.M.S. (President) with four civilian members of the medical profession appointed by the Secretary of State and the President of the Medical Board, India Office, when matters concerning India are under discussion. The ordinary meetings of the Board will be presided over by a chairman appointed by the Secretary of State from among the civilian members of the Board and nominated by the members in consultation with the D.G.A.M.S. If the D.G.A.M.S. desires to attend any meeting of the Board he will take the chair.

The Board will meet three a year but the civilian members may arrange additional meetings on notifying the D.G.A.M.S. through the chairman. After each meeting the conclusions of the Board will be reported to the D.G.A.M.S. and after further consultation if necessary by him to the Secretary of State. Whenever he desires to do so the Secretary of State will see him or any of the civilian members of the Board and the Board will have the right after informing the D.G.A.M.S. of access to the Secretary of State.

The following have been appointed to the Board as now constituted: Lieut. General Sir Matthew Fell, D.G.A.M.S. (President); Sir Berkeley Moynihan, Bt., P.R.C.S. (Chairman); Lord Dawson of Penn, M.D., Sir Cuthbert Wallace, F.R.C.S., Professor D. P. D. Walker, F.R.C.S., with Sir Leonard Rogers, M.D., F.R.S., President of the Medical Board, India Office, when matters concerning India are under discussion. The Secretary is Major C. M. Drew (D.A.D.G.A.M.D.). Vacancies among the civilian members will be filled by the Secretary of State on the recommendation of the remaining members of the Board.

Army Medical Directorate Consultative Committee

It has been decided also to appoint a committee, to be known as the Army Medical Directorate Consultative Committee, to advise the D.G.A.M.S. as to (a) the supply of candidates for the regular R.A.M.C. and its reserves, (b) post-graduate and other professional courses of instruction for R.A.M.C. officers, and (c) such administrative or professional questions as may from time to time be referred to it. The chairman will be the Director-General A.M.S. and the vice-chairman the Deputy Director-General A.M.S. There will be six civilian members of the medical profession who hold instructional or other appointments at university centres or medical schools and one civilian member of the Chemical Warfare Committee. The civilian members will be appointed by the Secretary of State on the nomination of the D.G.A.M.S. every three years. Full meetings of the committee will be held twice yearly, or as often as may

be required at the War Office. Other meetings may be held elsewhere, as required.

The Secretary of State has approved the following appointments to the committee: Lieut-General Sir Matthew Fell (chairman), Major-General H. B. Fawcus (vice-chairman), Sir Robert Bolam M.D., Sir E. Farquhar Buzzard, M.D., Professor T. R. Elliott, M.D., F.R.S., Professor J. Fraser, F.R.C.S., Professor G. E. Gask, F.R.C.S., Mr. A. E. Webb-Johnson, F.R.C.S., Professor J. Barcroft, F.R.S. (Chemical Warfare Committee). Major C. M. Drew is secretary of this committee also.

No 14 STATIONARY HOSPITAL

The annual dinner of the No 14 Stationary Hospital was held at the Trosadero Restaurant London on December 7th. Colonel C. R. Evans D.S.O. took the chair, and proposed the toast of

The Hospital. He described the way in which No 14 Stationary Hospital came into existence at the beginning of the war, and touched lightly on some of the vicissitudes in its career. He referred warmly to the spirit of comradeship which had always characterized it and which continued to attract each year to the annual dinner a gratifying number of the hospital staff. Dr. H. L. Tidy, the organizer of the dinner, read letters from several medical officers who were unable to attend. A hearty vote of thanks was accorded to him for his services in keeping these pleasant functions in existence.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE House of Commons this week passed a resolution allocating time for the committee and subsequent stages of the Local Government Bill and the Local Government (Scotland) Bill and completed examination of the Imperial Telegraphs Bill. Other business put down for the week included the first day of the committee stage of the Local Government Bill and debate on Mr. Chamberlain's proposal to reduce the housing subsidy after next September. The House eventually decided to allot seventeen days for the Local Government Bill as follows: committee thirteen, report three, and third reading one. Twelve more days were allotted to the Scottish Bill—namely, committee nine, report two, and third reading one. [Originally only eight days were proposed by the Government for the committee stage of the Scottish Bill, but Sir J. Gilmour agreed to give an extra day.]

Representatives of the Poor Law Committee of the British Medical Association met the Parliamentary Medical Committee at the House of Commons on December 11th to discuss possible amendments to the Local Government Bill. The Scottish Bill on the same subject was not considered by the conference. Certain amendments proposing to give effect to the views of the Poor Law Committee have been, or will be, put down by Dr. Fremantle, Sir Richard Luce and other members, but do not come before the House as the proposals of the Parliamentary Medical Committee. On Clause 4, which deals with the alternative powers of giving assistance the Poor Law Committee denied that it should be obligatory, instead of optional, on local authorities to give assistance under the Public Health Act, Mental Deficiency Act, Maternity and Child Welfare Act, Blind Persons Act and Public Health (Tuberculosis) Act, by virtue of the appropriate Act, and not by way of poor relief. Amendments proposing this are already on the paper. The future of institutions taken over by the public health authorities was also mentioned in the discussion, and a desire expressed that they should not be run as Poor Law infirmaries but as public health hospitals. A suggestion was made that the mandatory character which the conference desired Clause 4 to have should be qualified by giving the Minister a right to waive the obligations of the local authority on application being made to him and a case proved. The bill already proposes to give him similar power to waive the obligation of appointing whole time medical officers.

Discussion arose on the proposal in the bill to include health services in the block grant to local authorities. Some medical members of Parliament argued that child welfare and maternity services should be excluded from the block grant in the first five years but the representatives of the Poor Law Committee of the British Medical Association thought a compromise might secure that additional grants would be made where large developments occur in maternity services and child welfare. The conference was of the general opinion that the provisions of the bill regarding the block grant might be augmented by the Minister taking power under Clause 86 to see that councils provided efficient public health services.

The representatives of the Poor Law Committee indicated that they approved the main principles of the bill, subject to ratification of this view by the Council of the British Medical Association which was due to meet on the following day.

Local Government (Scotland) Bill.

The House of Commons discussed on December 5th, a money resolution authorizing the expenditure involved in connexion with the Local Government (Scotland) Bill. After Dr. Elliott had explained the objects of the resolution, Mr. Cowan wished to know what power the Government had taken to assist new social services which might be started during the quinquennial period. Was any money available in Scotland which could be used for expanding or for new services?

Dr. DRUMMOND SMITH said he was disappointed that Dr. Elliott had given no justification for the proposal to finance health services by bringing them into the ambit of a block grant instead of allowing them to continue under the percentage grant system. No town or country district in Scotland had yet a really adequate public health system nor had an excessive amount of money ever been spent in any such way. The bulk of the total grants was still to be paid under the percentage system but health services were to be put under the block grant system. Health services were the most rapidly developing of public services, within the last twelve years more subjects had been brought within their scope, and the expenditure on them had in some cases increased two or three times. His friends believed that the Minister of Health and Dr. Elliott were not unsympathetic to these services but he suspected that the Treasury had adopted the block grant as a means of checking rapidly developing services which were likely to expand still more. Public opinion was ripe for a still larger development, and on local authorities some of the keenest workers on the public health side of local government were Conservatives. In many of the large towns of Scotland the present and the preceding year had been "economy years" yet this year was to be taken as the standard under the bill. Therefore if any development of services now in existence was undertaken within the next five years, the expense would fall on the ratepayers.

There was no child welfare service in Cathness nor in a number of other districts of Scotland. Did the Government expect that any district which had no child welfare and maternity service at present was likely to establish one within the next five years, seeing that to do so would involve a great increase in the local rates? Figures showed that in Edinburgh last year there were many more deaths among mothers who had no ante-natal treatment than among those who had. The significance of this was just being realized where the service was not adequate and where it had not been taken up at all. If the whole of the public health services could not be taken out of the block grant could not child welfare and maternity at least come under the percentage system? No probable development of child welfare and maternity service could be regarded as excessive. Maternal mortality had been receiving special attention and two Commissions were inquiring into it at present. Many factors in maternal mortality were not understood and there were great difficulties in regard to it. One obvious factor, however, was that women who received attention before confinement had a much greater chance of surviving. The House and the country would be grateful if these services were removed from a stagnating influence. Dr. Shiels closed with a reference to a cognate matter. For years past the House and the Scottish Board of Health had put various new duties on local authorities. These authorities now had to supply insulin they had a new duty with regard to encephalitis and they did not know what other new duties would turn up they would have to put on the communities the whole expense of new services which the House or the Board of Health might call upon them to provide.

Mr. W. WATSON (Lord Advocate) said that by the percentage grant Parliament was at the mercy of richer districts, and penalized the poorer. That was a vital point when considering the adequate provision of public services including health services. Sir John Gilmour was as concerned as was Mr. Chamberlain to see maternity and child welfare schemes fully and adequately protected and carried out.

The House then carried the financial resolution by 224 to 140.

Preservation of Infant Life Bill.

This bill was considered by the House of Lords in Committee on December 6th. Clause 1 provided that

Any person who with intent to destroy the life of a child capable of being born alive, by any wilful act causes a child to die before it has an existence independent of its mother shall be guilty of felony, to wit child destruction, and shall be liable on conviction thereof on indictment to penal servitude for life. It is provided that no person shall be convicted of an offence under this section if it is proved that the act which caused the death of the child was done in good faith for the purpose only of preserving the life of the mother.

A further subsection provided that evidence of twenty-eight weeks pregnancy at any material time should be prima facie evidence that the woman was at that time pregnant of a child capable of being born alive.

Lord ATKIN moved to omit Clause 1 in order to insert the following new clause

1—(1) A woman may be convicted of infanticide notwithstanding that the death of her child is caused by her in the course of delivery, and the term "infanticide" in this bill shall mean infanticide Act 1922, shall include a child while in the course of delivery. (2) For the purposes of this Act the course of delivery shall be deemed to continue until the child has an existence independent of its mother.

Lord Atkin, in moving his amendment said he had previously objected to the bill on the ground that it went further than was necessary and that it exposed professional men to the danger of being charged with a new offence which it was unnecessary to put upon the Statute Book. He was prepared to accept the view that

a gap existed in the law and that whereas at present a woman could only be convicted of an offence if a child who was killed had a separate existence, there might be cases in which the death was caused while the child was in the act of being born. That gap ought to be remedied and his amendment precisely provided for the position by proposing that the offence of infanticide should be extended. The bill went further. It extended the offence to third persons other than the mother. He was reluctant that a new offence should be created which would expose professional men and women to the possibility of a charge of this kind. From time to time the doctor had to make up his mind that to save the mother's life the child must be sacrificed. This bill would make such a doctor liable to a new offence, punishable by penal servitude for life unless he discharged the onus of showing that he acted in good faith for the purpose of preserving the life of the mother. Lord ATKIN objected strongly to any onus being put on anybody to prove he was innocent. It was very inadvisable that professional men and women should carry on their important vocations under the possibility of a criminal charge either by a disappointed parent or a mischievous attendant. Another objectionable provision in the bill was that the offence was extended to the killing of a child before delivery had begun. That was an unnecessary proposal, which would overlap the existing law on procured abortion. For these reasons Lord ATKIN proposed that the bill should be confined to meeting the only evil which really existed, and that this evil should be met by slightly extending the bounds of an old offence.

Lord MERRIVALE said he was not prejudiced against any proposal for dealing by an independent method with the grave danger at which this bill was aimed. Lord ATKIN's amendment would reduce to a misdemeanour the limited offence which it created. The loophole for evasion of the long-established severity of the criminal law towards abortion which had been pointed out by Mr Justice Talbot had not been till then generally appreciated. Lord DARLING had framed a bill in a previous session which had been accepted by the House of Lords on principle and sent to a Grand Committee. That bill was designed to provide that, in the case unprovided for by the penalty of abortion should be incurred by those engaged in the act. No person of any experience wished to imperil a decent doctor who had performed a terrible task and had deprived a fellow creature of life but as Lord MERRIVALE conceived it, the respectable medical practitioner and the decent midwife did not run this risk, but the people who at present practised abortion and in a vast number of cases escaped without penalty because the crime was most difficult to bring home. The House of Lords would provide for the security of the respectable medical practitioner and the respectable midwife if a clause or subsection were inserted to provide that there should be no prosecution of a registered practitioner or of a registered midwife without the sanction of the Attorney General.

Lord PARSONS said the question of the doctor or the nurse was a distinct one. For reasons which they all knew they had not the advantage of hearing the views of Lord Dawson of Penn. He thought the bill as it stood was unduly harsh.

Lord DARLING said that at present a woman who desired not to have a child born alive and continue to exist could go to a professional abortionist of whom there were many and say:

I expect my delivery about a certain time. When I know it is coming I shall send a message to you. I only ask you to do what is perfectly safe. Before it has a separate existence, when it is neither a living soul nor merely a foetus you kill it, and by the law of England you commit no offence whatever. If Lord ATKIN's amendment were carried that monstrous condition of things would still be the law of England. Lord DARLING had spoken to learned judges and had found that there were far more of these cases than people who did not attend as was suspected. On the question of proving onus the provision in Clause 1 running:

if it is proved that the act which caused the death of the child was done in good faith for the purpose only of preserving the life of the mother did not say that this must be proved by the defence. Lord DARLING offered at the proper time to move to alter the provision to read: provided that no person shall be guilty under this section unless it is proved that the act was not done. That would put on the prosecution the obligation to prove that the person who did the act had not done it only to preserve the life of the mother.

Lord HAILSHAM, the Lord Chancellor, said that by English law a child had not a separate existence by reason of the fact that it had breathed. It had to be proved to have acquired a separate and distinct circulation from that of its mother. If the life of a living thing be taken after the commencement of its birth but before it had acquired a separate existence in the sense indicated then at present there was no offence at all. Nobody could be punished if proved to have done it, however maliciously and wickedly. He had expressed regret that publicity had been given to the existence of this gap but the gap having been disclosed it was incumbent to close it. Unfortunately there were people who made of abortion a trade profitable in proportion to its danger. The practice of abortion was very rife in this country at present, and Lord ATKIN's amendment would provide the abortionist with a charter. Some provision had been made in the bill to cover the doctor who acted in good faith, but Lord HAILSHAM thought it advisable to go further. He advised Lord DARLING to accept or introduce an amendment making clear that the doctor was not charged with the burden of proving he acted in good faith, or else to accept the suggestion of Lord MERRIVALE that no prosecution should take place under this bill without the fiat of the Attorney General which would be an adequate protection. When once Parliament had made clear that so long as the act was done in good faith it was no criminal offence he did not think they would embarrass the medical man. It was necessary sometimes to procure abortion for the sake of the mother, and he had never

heard that any doctor had been embarrassed or had hesitated in the discharge of that duty by reason of the knowledge that if he was not acting in good faith he would be guilty of a criminal offence. He did not think the embarrassment at all would be greater under this bill than under the existing law but care must be taken that the offence was not made to extend further than was necessary. He advised Lord DARLING and the House to make that clear now or on the report stage. The Infanticide Act said that a woman would otherwise be a murderer should be a less offence when the person murdered was a newborn child and when the mother who had taken its life was disturbed and unbalanced in her mind by reason of having just given birth to the child. Lord ATKIN's amendment would mean that if the woman's mind was not up to it and if she did the act in cold blood deliberately then she would commit no offence at all. The Infanticide Act did not create an offence but modified a penalty. The bill before the House created an offence which had been made penal in the Indian criminal code many years ago.

Lord ATKIN said that both as a judge and a president of the Medical Legal Society he had expressed himself against the offence of abortion. His objection to the bill was that it minimized that offence because that which corresponded to abortion under this bill would only be an offence if done with the intention of procuring the death of a child which was not an ingredient in an ordinary case of abortion. He did not believe there was a single instance known of a professional abortionist killing a child in the course of delivery. If that had happened it would have been discovered at coroners' inquests. He was prepared to accept that there were many more cases than the public knew where the mother had killed the child in the course of delivery.

By 40 votes to 11 the Lords decided that Clause 2 in its original form should stand part of the bill. The House then agreed to the remaining clauses.

Outdoor Relief in Distressed Mining Areas

Lord EUSTACE PERCY spoke on December 5th in reply to Mr. Wilkinson who, on a motion for the adjournment of the House, had urged the provision from public funds of clothes for children in the distressed mining areas. Lord EUSTACE said that in practically the whole of Glamorgan feeding of necessitous children was now done on medical certificates. In Rhondda over 1,000 children were being fed on medical certificates. A few weeks ago he sent down a medical officer who reported that the work was thoroughly well done and that it was necessary for the medical examination to be continued. That was being done and reports to Lord EUSTACE were that serious deterioration among the children from malnutrition was being prevented. As regards boots, the needs of the school children in South Wales had been met by voluntary effort up to now. The chief and urgent need in the schools of South Wales was clothing. Feeding of the kind he had described was going on in Northumberland but nothing was being done in Durham.

Answering questions on December 5th, Sir HENRY WOOD said that in parts of the coal mining areas as elsewhere outdoor relief was given by the guardians to able-bodied men only on a medical certificate. This was a matter within the discretion of the guardians. Lord EUSTACE PERCY announced on the same day that most education authorities in mining areas including eleven in South Wales were providing meals or other nourishment to children suffering from malnutrition whose parents could not provide them with sufficient food. In Monmouth and Aberllynny feeding was on an income scale and in the rest of Wales on a medical certificate on the state of the child's health. Medical examinations were frequent and arrangements were made so that any child who became malnourished between two medical inspections could be fed. He had made a specific recommendation on the amount of time that ought to elapse between inspections. Feeding in the distressed areas should be based on close and continuous medical inspection of the child. The areas which were doing that were doing much more satisfactory work than areas which merely fed on the basis of the poverty of the parents.

Lord EUSTACE PERCY on December 10th told Mr. James Hudson that of twenty local authorities in the mining districts of South Wales and Durham twelve were already providing meals for school children, two were preparing to do so and six were not so far as he knew providing any meals. Five of the authorities providing meals were doing so on a medical basis of selection and one other authority was preparing to adopt this basis. Some months ago he communicated with the local education authorities in other mining areas suggesting that a special medical survey of the schools should be made before the end of the summer term. As a result of this survey feeding had now been undertaken in certain of these areas also. Children selected on a medical basis might be provided with ordinary dinners or with special nourishment, such as milk and cod liver oil and malt. On many occasions during the course of the last year he had emphasized the importance of local authorities making adequate provision for malnourished children and had pointed out some of the advantages of the medical basis of selection as compared with the income basis but had put no pressure upon them to adopt the former in preference to the latter. When the medical basis was adopted he had urged that borderline cases should be re-examined at frequent intervals and that the schools as a whole should be periodically re-surveyed. In certain cases arrangements were also made for the temporary feeding of children between the visits of the medical officers if the head teacher had reason to believe that any child was not receiving sufficient food. The distinction which appeared to be drawn by Mr. Hudson between medicinal feeding and feeding children who were hungry was based on a misapprehension. Malnutrition for this purpose meant that the child was unable by reason of

lack of food to take full advantage of the education provided for it. That was the test prescribed by the Education Act, and the distinction was between selection on this basis by medical inspection and supervision of the children themselves and selection according to the size of the parents' income.

Vaccination against Distemper in Dogs

Replying to Mr Crawford on December 10th Mr GUINNESS said the Field Distemper Research Committee had recently announced that an effective method of vaccinating dogs against distemper had been discovered. He understood that the committee had offered to assist commercial laboratories or institutions willing to prepare the vaccine and make it available to the public. No public funds were available to assist the preparation or distribution of the vaccine. The Ministry's responsibility in respect of diseases of the dog was confined to diseases such as rabies, which were communicable to farm livestock or human beings.

Mr CRAWFORD asked whether if this was an effective preventive it did not mark a milestone in the treatment of dogs and if the Government could help in the efforts which were being made in this direction by recommending a grant to help to make the application of the vaccine universal? Mr GUINNESS said he agreed as to the great importance of this discovery, but he did not see any necessity for a Government grant seeing that the discovery was now past the experimental stage and there was every hope that it would be taken up in the ordinary course by those whose business it was to supply these vaccines. Dr VERNON DAVIES: Is it not a fact that this is a direct result of experiments made on dogs? Mr GUINNESS: I believe that is so.

Health of the Mercantile Marine.—Mr HERBERT WILLIAMS, in a reply to Dr Vernon Davies on December 5th said that as a result of consultations between the Ministry of Health and the Board of Trade a joint standing committee had been set up to advise the two departments on matters affecting the health of the mercantile marine. One of the first questions which that committee would be asked to consider was the preparation of a report on the health of the mercantile marine.

Women Members of Visiting Committees of Mental Hospitals.—Mr CHAMBERLAIN told Sir Robert Newman on December 6th that information was not available to show how many women patients of unsound mind were detained in borough or county mental hospitals in England or Wales where there were no women members on the visiting committee. When legislation dealing with the subject was proposed the Government would consider making it compulsory that a certain number of women should be appointed to serve on all such visiting committees.

Bellahouston Hospital.—Major TAYLOR in reply to Mr Buchanan on December 6th said the tenure of Bellahouston Hospital by the Ministry of Pensions would not extend beyond Whitsuntide, 1930. It was impossible so soon to indicate the steps that would be taken to accommodate patients who might then require hospital treatment. No difficulty was anticipated in making satisfactory arrangements. He would continue to maintain hospital accommodation in the West of Scotland as long as possible.

Notes in Brief

Mr Chamberlain is considering the setting up of an advisory committee on the question whether certain articles ordered for insured persons by insurance practitioners are foods and cannot properly be supplied to insured persons as part of their medical benefit under the National Health Insurance Acts. He hopes to provide for the representation of Wales on the committee.

The protocol prohibiting the use of gas in war has only been ratified by six States of which Germany is not one. The British Government is not prepared to ratify it unless all other signatories are willing to do so.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a congregation held on December 7th the following medical degrees were conferred:

M.D.—W. Haw
B.Chem.—H. N. Webber, H. Girling.

UNIVERSITY OF LONDON

The regulations in the Faculty of Medicine for internal and external students have been amended by the addition of the following words at the end of the section headed Branch III—Psychological Medicine:

A general knowledge of medicine will be expected of the candidates and questions in general medicine may be set.

Mr H. L. Eason has been elected chairman of the Library Committee.

The Geoffrey E. Dineen Travelling Studentship in Otorhinolaryngology of the value of £450 will be awarded annually. The tenure is for one year to be spent abroad in accordance with the scheme to be approved by the Board. It may be extended for one or two years and during the extended period the student may be allowed to undertake research at the Royal Ear Hospital or some other approved laboratory. Grants for the promotion of research in otorhinolaryngology or any part thereof may be made from the trust fund of the benefaction. No person shall be qualified for

election to the studentship or to receive grants from the fund until he or she has obtained M.B., B.S. degrees in the University. Applications on forms provided to be sent to the Academic Registrar of the University by December 31st, 1928 together with a statement of the nature of the research in which the student proposes to engage or a scheme of study submitted for the approval of the Board.

Sixteen medical entrance scholarships and exhibitions of the aggregate total value of £1700 tenable in the Faculty of Medical Sciences of University College and King's College and in the medical schools of King's College Hospital, University College Hospital, the Loudon Hospital, and the London (Royal Free Hospital) School of Medicine for Women will be offered by the London Inter-Collegiate Scholarships Board. The examinations for medical scholarships will commence on April 16th and June 25th 1929. The latest dates for the receipt of entries are March 21st and June 11th respectively. Further particulars and entry forms may be obtained from the Secretary of the London Inter-Collegiate Scholarships Board, S. C. Rauer, M.A., the Medical School, King's College Hospital, Denmark Hill, S.E. 5.

UNIVERSITY OF BIRMINGHAM

Dr. L. G. PARSONS has been appointed the first occupant of the new Chair of Infant Hygiene and Diseases of Children.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examination indicated:

M.D.—C. B. Perry, (Dissertation Approved) A. M. Critchley.
FINAL M.B., B.Ch.B. (Part I including Forensic Medicine and Toxicology):
—J. P. Coates, E. J. M. D. Colloso, H. F. G. Corfield,
—J. L. W. Davies, J. J. J. Gerald, E. D. Jones, G. F. Langley,
R. A. Lacey, R. P. Lucas, J. F. Newton, S. C. Wake (in Part I only),
U. M. Hopkins, W. L. Sleight, H. M. Stover (Part II),
A. A. Dowling, H. D. Pyke, I. G. R. Pells, F. H. L. Redman
(in Group II completing examination) Phoebe C. Vine.

* With distinction in Materia Medica, Pharmacology, Pharmacology and Therapeutics and Forensic Medicine and Toxicology.
† With distinction in Forensic Medicine and Toxicology.
‡ With distinction in Materia Medica, Pharmacology, Pharmacology and Therapeutics.
§ With second-class honours and distinction in Obstetrics.
¶ With distinction in Public Health.

UNIVERSITY OF GLASGOW

PROFESSOR ANDREW HUNTLY, M.A., B.Sc., M.B., Ch.B., of the University of Toronto has been appointed Gardner Professor of Physiological Chemistry in the University of Glasgow, in succession to Professor Cathcart, F.R.S.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following candidates have been approved at the examination indicated:

FINAL MEDICAL EXAMINATION, Part II, Medicine (M.B.)—A. G. Thompson, W. J. E. Jesson, N. A. Stack, G. O. Dockery, D. F. Walsh, M. M. Finegan, J. E. C. Cherry, J. E. McMahon, J. T. McGinn, I. W. Pigott, E. F. S. Morrison, C. M. O'Brien, Surgery (B.Ch.)—A. G. Thompson, G. C. Dockery, D. F. Walsh, W. B. Johnston, J. E. McMahon, E. M. P. Molloy, N. Shapira, R. I. G. Reid, J. Beggs, F. R. Falkner, I. P. Battaglia, J. Herwich, C. M. K. B. S. Mackenna, Midwifery (B.A.O.)—L. B. Harris, T. B. McMahon, G. B. Thrift, O. M. Taylor, R. B. J. Esbom, B. H. Hamilton, C. M. O'Brien, I. Reid, A. H. O'Malley, E. B. A. Solomons, N. S. Blass, G. K. Graham, J. Beggs, A. F. Kennedy, P. A. Thornton, F. B. Mackenna, W. L. Chapman.

* Passed on high marks.

NATIONAL UNIVERSITY OF IRELAND

The Senate at its meeting on December 7th tendered to the relatives of the late Dr. Michael M. Davitt its respectful sympathy in their recent bereavement.

It was decided to hold an examination for a travelling studentship in pathology next year in view of the fact that the examination for 1928 had not been completed for.

The following appointments at University College, Dublin were made: Professor of Surgery, Senator L. Barnhill; M.D., M.Ch., Professor of Systemic Surgery, H. S. Meade, F.R.C.S.I., Lecturer in Medical Jurisprudence, A. R. J. Dunagan, M.D.

A report from Dr. D. J. Coffey as representative of the University on the General Medical Council was approved.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary Council meeting was held on December 5th when the President, Sir Berkeley Moynihan, Bt., was in the chair.

Diplomas and Licences

Diplomas of Fellowship were granted to the following thirty six candidates:

J. R. M. Wigham, A. W. Holsate, B. L. B. Jefferson, J. H. Dozart, H. S. Allen, F. S. Page, T. V. Pearce, F. W. G. Nash, A. M. Clay, J. O. Barrett, V. G. G. W. Walker, V. H. Ellis, D. H. MacLeod, A. McWilliam, J. P. Monkhouse, G. H. Steele, C. B. Andrew, C. F. Beare, L. Price, A. Sourash, H. B. Stallard, T. B. Crabtree, J. M. Turner, G. E. Lark, C. I. Tuckett, L. A. Richardson, R. W. Butler, M. A. Hussell, J. M. Buchanan, I. Crooks, G. M. Gray, Dorothy W. Hall, J. S. Loughridge, C. McI. Marshall, S. V. Taylor, J. J. Walsh.

R C Brock, I D Miller and J T Sykes also attended the examination at the Final Fellowship Examination but have not yet complied with the regulations.

Diplomas of Membership were granted to A S Rajasingham and I Larence Whitrow, who have now complied with the regulations. Licences in Dental Surgery were granted to forty eight candidates.

Court of Examiners

Mr Ernest W Hey Groves was elected a member of the Court of Examiners in the vacancy occasioned by the resignation of Mr V Warren Low.

Annual Meeting of Fellows and Members

A report from the Committee on the Annual Report of the Council was received, and the comments recommended by the Committee regarding the resolution carried at the annual meeting of Fellows and Members were approved and adopted as follows:

In view of the recent postal vote of the Fellows the Council is not prepared to take into further consideration at the present time the question of altering the constitution of the College so as to give Members of the College direct representation on the Council.

The main function of the College is to promote the study and practice of surgery. If there are any matters in this connection affecting the health of the nation to which Members of the College wish to draw attention an opportunity for so doing is afforded at the annual meeting of Fellows and Members. While the Council will at all times welcome and give careful consideration to representations made to it by any Member or body of Members of the College in reference to matters which come within the functions of the College.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

The annual meeting of the Royal College of Physicians of Edinburgh was held on December 6th. Dr Robert A Fleming was re-elected President for the ensuing year. Dr Robert Thim was nominated Vice President and Drs G Loriel Gulland and John Orr William Loryce Edwin Bramwell, and A Iergus Heyat were elected to form the Council.

Drs William Russell and John Orr have been re-elected representatives of the College on the Board of Management of the Royal Infirmary of Edinburgh.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly business meeting held on December 7th, the 1 resident admitted to the Licences in Medicine and Midwifery, the following candidates who had passed the Winter Conjoint Final Examination: D J Herriek, J I Ryne, J P J MacMahon, L B O Sullivan, J Ryan, W J Walshe. It was unanimously resolved.

That the Committee of Management of the Conjoint Scheme of the Irish Royal Colleges of Physicians and Surgeons be requested to proceed with whatever steps should be considered necessary to establish reciprocity with the National Board of Examiners of the United States.

Medical News.

A PORTRAIT of Professor Priestley Smith LL D, F R C S, will be unveiled to day (Friday, December 14th) at the Queen's Hospital, Birmingham.

At a meeting of the Royal Anthropological Society to be held at 52, Upper Bedford Place, W C, on Tuesday, December 18th, at 8.30 p.m., Miss R M Fleming will give an address, illustrated by lantern slides entitled "A study of growth in children. Its ethnological and educational significance. An analysis of six years' consecutive measurement."

At a meeting of the Royal Statistical Society on December 18th, in the hall of the Royal Society of Arts, Adelphi, W C 2 at 5.15 p.m., Mr H E Soper will read a paper on the interpretation of periodicity in disease prevalence.

THE house and library of the Royal Society of Medicine will be closed from Saturday, December 22nd, to Thursday, December 27th, both days inclusive.

As announced in our advertisement pages, the Grocers' Company are offering scholarships of £300 a year to encourage original research in sanitary science. An allowance is also made to meet the cost of apparatus and other expenses in connexion with the work. The scholarships are renewable for one year, but renewable for a second or third year. The election will take place in May, 1929. Applications must be sent in before the end of April to the Clerk of the Grocers' Company, Grocers' Hall, London E C 2, from whom forms of application and further information may be obtained.

A JOINT gift of £20,000, payable over the next eight years, has been made by Sir William Berry and Sir Gomor Berry in response to the special appeal for £55,000 to rebuild the two wards of the King Edward VII Hospital, Windsor, recently destroyed by fire, and the erection of a new nurses' hostel. A sum of £12,000 is still required.

We are informed that about forty vacant beds are available for nursing and convalescent children of the professional classes at the Yarrow Convalescent Home at Broadstairs. The nominal weekly charge per child is £1 or less, the balance of the cost of maintaining the home being met by the founder, Sir Alfred Yarrow. Professional societies, parents, and doctors are invited to obtain particulars from the secretary, 116, Victoria Street, S W 1.

THE tenth annual dinner of the Royanment Unit of the Scottish Women's Hospitals was held at the Belgravia Hotel, London, on December 1st, under the presidency of Miss Frances Lyons, M S. Seventy four members attended.

THE council of the Oxford Ophthalmological Congress has elected Mr Bernard Cridland as master for the coming year, the deputy master being Mr Philip H Adams, the honorary treasurer Mr Robert J Coultter, and the honorary secretary, to whom all communications should be addressed, Mr C G Russ Wood, 12, St John's Hill, Shrewsbury. The dates of the next Congress are July 4th, 5th, and 6th, 1929.

THE report of the Food Investigation Board for 1927 has been issued by the Department of Scientific and Industrial Research (price 4s net). It gives an account of the various activities of the Board during the year under review, and in particular describes the progress of investigations not sufficiently advanced to warrant the issue of special reports. The report is divided into two sections, the first of which is a report of the Board, while the second is a report by the Director of Food Investigation. The latter is subdivided into sections, each written by the member of the staff responsible for the conduct of the particular investigation, the progress of which is described in that section.

A REPORT on phlebotomy and Oroya fever and venous pyemia, by the late Dr Hideo Noguchi and three colleagues, is published in the issue of *Science* for November 23rd.

THE annual report of the Commissioner of Public Health, Queensland, for the period ending June 30th, 1928, contains a note that the outcome of the disaster at Bundaberg has been that immunization by toxin antitoxin has ceased throughout the State of Queensland and that at present it is not possible to make use of a well tried and most effective method of controlling diphtheria.

We have received the first three issues of *Clinica*, a bi-monthly journal published at Bucarest under the patronage of professors in the medical faculty and the editorial direction of Dr B Theodorescu. Each issue consists entirely of original articles written in Rumanian with French summaries appended, and is devoted to some particular subject such as cardiology, alimentary diseases, and surgery respectively.

THE December issue of the *Mission Hospital* contains the annual financial statement of the Medical Missionary Auxiliary of the Church Missionary Society, from which it appears that there is a surplus on the year's working of £4,276, to which may be added £1,420 available for allocation from the surplus of the previous year. This has enabled increased grants to be given to some of the more needy mission hospitals overseas. Owing to the difficulties of the war years there is an outstanding deficit of £19,000. The present increase in income is attributed to the expansion of the bodies which support the Medical Missionary Auxiliary, since receipts from legacies have decreased this year by £7,000.

At the recent congress held at Bordeaux under the name of *Journées Médicales de Bordeaux*, the following papers, among others, were read: New treatment of pulmonary emphysema and asthma by Dr Croix; malignant carcinoma and naevi by Professor Sahrazès; aceto diurnal by Professor Abadie; new ideas on scarlet fever by Professor Dupérier; electrotherapy of infantile paralysis by Dr Roques; arterial encephalography and localization of cerebral tumours by Professor Egas Moniz of Lisbon; and treatment of bone and joint tuberculosis by Professor Rocher.

THE third congress of the German Society for Combating Rheumatism was held in Berlin from November 5th to 8th, under the presidency of Professor Dietrich, when the following papers among others were read: Local disease of the teeth and rheumatism, by Professor Adlon; pseudo rheumatism, by Professor G v Bergmann; rheumatic eye disease, by Professor L Krülowmann; etiological diagnosis and treatment of chronic joint disease, by Dr A Zimmer; treatment of rheumatic contractures, by Professor H Gocht; chronic joint disease, with special reference to articular syphilis and Still's disease, by Professor H Strass; and diagnosis and treatment of chronic joint disease, by Professor H Umber. The next congress will be held in the middle of April at Wiesbaden. Further information can be obtained from the secretary, Dr Max Hirsch, Fraunhoferstrasse 16, Charlottenburg.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are MUSK 11 9861, 9862, 9863, and 9864 (internal exchange four lines).

The TELEGRAPHIC ADDRESSES are
EDITOR of the *British Medical Journal* Antology Westcent, London

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements etc.), Articulate Westcent London
MEDICAL SECRETARY Medisacca Westcent London

The address of the Irish Office of the British Medical Association is 16 South Frederick Street Dublin (telegrams *Pacillus Dublin*, telephone 62550 Dublin) and of the Scottish Office 7 Drumshough Gardens Edinburgh (telegrams *Associate Edinburgh* telephones 21361 Edinburgh).

QUERIES AND ANSWERS

DRY SKIN

"H M C" desires suggestions for the treatment of a woman, aged 40 who has had a very dry skin for a considerable time. She suffers each winter from deep cracks on the tops of the fingers and in the creases of the joints. Creams and ointments of various kinds and a course of thyroid gland, have been tried without much improvement.

A PAGE TURNING DEVICE FOR ARMLESS PATIENTS

With reference to W N's "Inquiry about a mechanical device for turning the leaves of a book." Dr W JOHNSON SMYTH (Bournemouth) and Dr F W BURTON FANNING (Norwich) remind us that among the many little inventions for the help of wounded officers who during the war were his guests the late Sir Arthur Shipley (Master of Christ's College, Cambridge) made an appliance of this kind suitable for a man without arms. It was held between the teeth and worked well. A description with figure appeared in the *British Medical Journal* of June 9th, 1917 (p. 769).

Mrs HUTCHINSON (The Lodge Pembroke College Cambridge) tells us that this contrivance was made by the Cambridge Instrument Company Ltd, Carlyle Road Cambridge during the war and it is possible they may still have the design and be able to repeat it. If not Mrs Hutchinson will endeavour to find a specimen contrivance or the design, which she believes to exist among Sir Arthur Shipley's papers.

INCOME TAX

Expenses of Caretaker Additional Practice

"J F M" is a bachelor, and as from October 24th purchased an additional practice. He continues to reside at his former practice where he employs a man and his wife as caretakers etc. and employs a widow at the additional surgery where she resides with her two children. What allowances is he entitled to?

On the facts stated "J F M" can claim the whole cost of the employment of the widow in respect of the additional premises—including of course any remuneration given in kind such as coal gas etc.—and the whole of the rent and rates. In the case of the premises where he resides, such expenses will have to be divided in a reasonable proportion, according to the ratio of private and professional use. We think that the income tax authorities will require the practice to be treated as a new one as from October 24th last, unless the additional net earnings from the new portion of the practice as now constituted are small.

Assistant's Motoring Expenses

A C F held various temporary appointments after qualifying in 1925 but has been in the same assistantship since November, 1926. He has been assessed as having commenced employment as from that date. He now uses his own car but for a considerable time a car was provided by his principal and a car which belonged to him was parked elsewhere. He also desires to know whether a man who books horses regularly through a commission agent can declare gallop or losses in his income tax return.

We are of opinion that in strictness the gallop of employment in such circumstances are separately computable for each employment and that expenses incurred in connexion with

care—either by way of renewal or through depreciation—are not deductible in respect of periods when it was not a condition of the employment that the car expenses should be borne by the employee. With regard to backing horses, the results, whether favourable or unfavourable to the backer, do not come within the scope of his income tax declaration.

LETTERS NOTES ETC

THE MEDICAL AND DENTAL REGISTERS OFFICE NOTICES

THE REGISTRAR of the General Medical Council (44, Hallam Street, Portland Place W 1) writes: In order to facilitate the work of those who find it essential to know whether a medical practitioner is legally qualified or not—snob, for instance, as officials of insurance committees, chemists and druggists, etc.—the Council publishes an office edition of the lists contained in the *Medical Register* giving the names and addresses of all registered practitioners. This office edition is bound in paper boards and issued from this office at the special rate of 7s 6d, post free, but no copies can be issued at this price unless they are ordered and paid for prior to December 31st of the year preceding that of publication. Similarly the Dental Board publishes an office edition of the *Dentists Register* containing the names and addresses of all registered practitioners and this local list at the price of 4s, not post free, but no copies can be issued at this price unless they are ordered and paid for prior to December 31st of the year preceding that of publication. This information may be useful to some of our readers.

THE DIAGNOSIS OF GASTRITIS

DR P J MOLLOY, in the course of a letter from Berlin writes: Considerations of space prevent my replying fully to Dr Hurst's criticisms of my letter of November 6th and I can therefore only deal with one or two points shortly. In his lecture he stated definitely that gastritis can be diagnosed only by means of a fractional test meal, and I suggested gastroscopy as an alternative method. The matter of gastroscopy being somewhat dangerous is beside the point. It is undoubtedly not the method of choice, but it is still a possible method. The radiological method is used by many people of experience and they are convinced it is the best finding it quite reliable in diagnosing gastritis. Therefore one may be allowed to take it that this method, although by no means perfect is another means of diagnosing this condition. And there are clinicians of wide experience who are convinced that gastrorrhoea is not a myth but a definite, if not too frequent, entity. I must still maintain my point of view that the primary essential factor of gastric and duodenal ulceration is not yet definitely known. I do not say that Aschoff is right, or that Bergmann is right, or that the infection theory is wrong, but am of the opinion that until the evidence of the guilt of any one factor is definitely proved the matter must be left open and there are not many who will maintain that the last word on the subject has been spoken. On the matter of milk test meals I went into the subject in detail with Kaik and I may mention that he is not satisfied that Dr Hurst's statements as regards his (Kaik's) work and findings are quite correct. And, finally, I hope Dr Hurst does not think I am, in medical matters, pro German and anti British: nothing is further removed from the truth. Having been some time in Germany I naturally am in more intimate contact with German than with English medicine but I do my best to keep in touch with medicine at home.

VAGINISMUS

A TASMANIAN CORRESPONDENT writes with reference to the inquiry by "G A" (September 8th, p. 473). Some thirty five years ago I had under my care a very bad case of vaginismus which had lasted five months. Under anaesthesia I inserted a fairly large boxwood egg shaped pessary, and impressed upon the patient the absolute necessity of removing it herself the next day by means of the strong tape left attached. I did not tell her anything about the size of the object left in her vagina. The plan was completely successful as also in two other cases later on. It is probable that the delivery while conscious of so large an object helps to correct the faulty psychology which is causing the trouble.

THE THERAPEUTIC VALUE OF VALERIAN

DR A ROSE (Aberdeen) writes to express complete agreement with Dr Manson's remarks about the value of valerian (*British Medical Journal* November 10th p. 842). I frequently use this drug in my work (he says) chiefly for patients suffering from neurosis. Unlike Dr Manson however, I prefer to prescribe with it ammonium bromide, occasionally sodium bromide but never potassium bromide. A typical prescription would be tr. valerianae ammon. draohm 1/2 bromide salt gr. x with perhaps a few grains of phenazone if the patient is suffering from headache that appears to be associated with the neurosis.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 48, 49, 50, 51, 54 and 55 of our advertisement columns and advertisements as to partnerships, assistantships and locum tenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 263.

An Address

ON

PERNICIOUS ANAEMIA

DELIVERED BEFORE THE WEST DORSET DIVISION ON
OCTOBER 30TH

BY

J. R. CHARLES, M.A., M.D., F.R.C.P.,

PHYSICIAN TO THE ROYAL INFIRMARY, BRISTOL

(Abridged)

PERNICIOUS ANAEMIA is a very mysterious complaint, the name of which may perhaps sometimes be changed, for it may exist without the specific anaemia which we recognize as pernicious. It has three main clinical modes of expressing itself, and perhaps when we know more about it we shall recognize more than three. It may appear clinically as a gastro-intestinal disease, or as a nervous disease, or as a blood disease, or as a combination of two or all of these conditions. Whether it need be as "pernicious" as it used to be is a question. Can anything be done to prevent its onset? Can anything be done to cure it? These are problems which will be discussed in this paper.

Last March a man, aged 61, was admitted into my wards with extreme prostration. One of his brothers, he said, was also extremely anaemic but as there has not been an opportunity of examining him it cannot be said that he also has pernicious anaemia. The left leg of the patient had been amputated many years previously for necrosis. For three years he had suffered from pains in the abdomen particularly in the epigastrium. These pains had no direct relation to food. He was also troubled with much intestinal flatulence. Six months before admission his pains disappeared. From that time he had developed increasing weakness during which period he vomited on several occasions. His appetite failed and he lost 2 st in weight. He lay in bed in a condition of extreme exhaustion and listlessness being so weak that he could hardly answer questions. He was very markedly lemon tinted. His tongue was clean but his teeth were carious. His heart sounds were very weak but there was no evident dilatation. There was diffuse tenderness over the whole of the abdomen but neither the liver nor the spleen could be felt. He had subcutaneous haemorrhages over his chest. No objective abnormality was found in his nervous system except that his knee jerk was extremely sluggish. His blood was pale and watery. A blood count showed

Red blood cells	2,400,000 per cmm
White cells	11,600
Haemoglobin	50 per cent
Colour index	0.65
Differential white count	
Polymorphonuclear	46 per cent
Lymphocytes	51
Eosinophils	1
Large mononuclears	2

Megalocytes were numerous and there were 3 normoblasts and 1 megaloblast to 100 white cells. Anisocytosis and poikilocytosis were marked. Van den Bergh's reaction gave "direct negative indirect" positive indicating a haemolytic anaemia.

A few days later he was given a transfusion which unproved his condition. He was so ill that he was given simultaneously all the remedies which might help him. These were arsenic dilute hydrochloric acid 30 minims three daily and liver. As he was unable to take this latter in a solid form he was given 2 drachms of the extract three times a day.

A month after admission he was very much better. His red cells at that time numbering 4,000,000 per cmm and his white cells 7,400. Ten days later his red cells numbered 6,500,000 per cmm. His colour changed entirely, the lemon tint disappeared and he left the infirmary in the middle of June with about 6,000,000 red cells per cmm and free from abnormal symptoms.

Since that time he has remained in good health until just recently but owing to his financial condition I do not think he has had sufficient food. He now complains of numbness and tingling in his hands.

This case is described in the briefest outline to draw attention to the family history of anaemia, the onset of his disease with abdominal trouble, the clean tongue, the extreme prostration, and certain points in treatment to which reference will be made later.

The disease may appear under very different guises—for example, as a cord lesion, the specific anaemia not being manifest till quite towards the end. Byrom Bramwell had a case of subacute combined degeneration of the cord in which the anaemia did not appear till about a fortnight before death.

There is, however, one outstanding feature in this complaint which is always constant, that being complete absence of free hydrochloric acid in the stomach. Lack of acid in

the stomach is a condition which is not very rare. Many people suffer from this, or perhaps do not suffer, because they may have no abnormal symptoms. It has, however, been pointed out that they are unduly prone to such complaints as appendicitis, cholecystitis, and rheumatoid arthritis.

All patients who develop pernicious anaemia have had an antecedent state of absence of free acid in their stomachs. It is quite probable that in many cases this lack of acid is an hereditary feature, and that this may be the reason why several cases of pernicious anaemia may be found among the members of one family. The nervous system is the seat of organic changes in over 80 per cent of all cases diagnosed as pernicious anaemia, the signs and symptoms of which may precede the blood changes.

These facts were brought to the forefront of this paper, and the anaemia is placed last, in order that the disease shall not be discussed merely as one of the blood, but rather as a very obscure complaint which affects the gastro-intestinal tract, the nervous system, and the blood. The blood is put last because it is so easy to make a mistaken diagnosis, and not to think of the possibility of pernicious anaemia when marked nervous or gastro-intestinal symptoms precede the haemic manifestations. As there is such a clinical condition as "leukaemic leukaemia," so there is such a condition as pernicious anaemia without anaemia, but probably never without gastro-intestinal trouble, for achlorhydria is almost, if not quite, a *sine qua non* of the disease.

At the very least, 80 per cent of the patients have symptoms directly referable to the gastro-intestinal tract, and many of these have suffered for many years before the anaemia is obvious. Out of 68 consecutive cases at Guy's Hospital I found that 45 had definite gastro-intestinal symptoms and that in 7 of these the symptoms dated back five or more years. For example, one, a man aged 57, had had diarrhoea and abdominal pain since he was 13, another aged 51 had suffered from similar symptoms since he was 25. These are not uncommon histories.

Achlorhydria is well known in many conditions, notably carcinoma, chronic gastritis, after severe infections, and from nervous causes. It may also, as we have seen, occur in apparently healthy subjects without giving rise to symptoms. When, however, symptoms do arise these are generally loss of appetite, morning nausea, a feeling of distension immediately after meals, heartburn, sometimes epigastric pain, and not infrequently diarrhoea.

Achlorhydria can only be recognized with certainty by gastric analysis. This has shown, by means of the fractional test meal that whereas many patients with so-called achylia gastrica secrete free hydrochloric acid during some period at least, of the process of digestion, cases of pernicious anaemia do not secrete free hydrochloric acid at any time.

A further interesting point has been described by Hurst and Bell—namely, that subacute combined degeneration of the cord may occur without the specific anaemia in cases of achlorhydria. As achlorhydria precedes all other symptoms of pernicious anaemia, we should know more about the secretions of our patients' stomachs, for it may be after all, within the realms of possibility that pernicious anaemia might be prevented from developing were free hydrochloric acid regularly administered to such people. Here we may note that the *British Pharmacopoeia* dose is much too small. If given at least 1/2 to 1 1/2 drachms is required, which may be taken in the form of a lemonade at meals.

Not only does achlorhydria precede the anaemia, but it is a permanent event persisting even during the natural remissions of the disease. Although as is so well known, the gastric mucosa frequently shows pathological changes in pernicious anaemia it has sometimes been found to be quite healthy though secreting no free hydrochloric acid. It would appear, therefore, that the deficiency lies in some underlying functional rather than structural cause and there is a good deal of evidence that it may be an inherited defect—a state which Hurst calls the "achlorhydric gastric diathesis." It has been found in relatives of patients who were suffering from pernicious anaemia and even in their children at as early an age as 6, or even 4.

The gastro intestinal symptoms of pernicious anaemia correspond very closely to those already mentioned in connexion with achlorhydria, though haematemesis may also occur, and the diarrhoea may be that of a definite mucous colitis. The tongue is frequently the seat of a glossitis, Hunter maintaining this to be so in every case. It is generally smooth, moist, and clean. So regularly is this the rule that a clean tongue associated with dyspepsia will suggest to our mind the possibility of pernicious anaemia, perhaps in the pre-anaemic stage, for a history of sore tongue may precede the recognition of the disease by years.

Cornell describes the case of a lady, one of his patients, who had seen him four months earlier complaining of nothing but nervousness, and who one day stopped him in the street to ask if he could do anything for her sore tongue. He asked her if she complained of anything else, to which she replied that her right foot was becoming so numb that she could hardly work the brake of her car. He examined her blood that day and found haemoglobin 60 per cent and 5,000,000 red cells per cmm, but a smear showed perfectly typical changes of pernicious anaemia.

One of this lady's male cousins had a sore tongue before seeing his doctor for weakness, and was also found to have pernicious anaemia.

If we now turn for a moment to subacute combined degeneration of the cord we find again that the nervous symptoms may develop long before the haemic manifestations. Very numerous observations have made it quite clear that the blood condition does not cause the cord disease. Moreover, there is no improvement in the nervous symptoms during the remissions in the blood state.

I have in my wards at the present time a man aged 43, who is suffering from this disease. He was a school porter, and says that he was an energetic man till a year ago. He then began to suffer from aching pains in his arms and legs which he called neuritis, and massaged them with oil. He has had these pains on and off ever since and for the last seven weeks pains in his chest causing difficulty in breathing.

There was no history of gastro intestinal trouble in this case. There was however a complete absence of hydrochloric acid in his fasting stomach, but a small amount was found one hour after a test meal. He has a marked lemon tint. A blood test showed red cells 1,200,000 per cmm, haemoglobin 35 per cent, colour index 1.4. Van den Bergh's reaction is indirect. The deep reflexes in his legs are very much exaggerated with a tendency towards an extensor response on the right but in addition to this he has a definite area of anaesthesia over the middle branch of his fifth nerve on the left side of his face, a very rare occurrence.

In the Mayo Clinic the nervous system was found to be involved in 80.6 per cent of 150 cases of pernicious anaemia. These figures agree with those of other observers. In many cases the ultimate fate of the patient depends much more on the nervous than on the haemic condition. Risien Russell, Batten, and Collier described three stages of the disease:

1. A stage of slight spastic paraplegia with slight ataxy and marked subjective sensations in the lower limbs. (Case 2.)
2. A stage of severe spastic paraplegia with marked anaesthesia of limbs and trunk.
3. A stage of complete flaccid paraplegia, absent knee-jerks, absolute anaesthesia, rapid wasting and loss of faradic excitability in the muscles of the paraplegic region, increase of superficial reflex excitability, absolute incontinence of both sphincters and oedema of the lower extremities and trunk.

The transition of one stage to the next may be remarkably abrupt. Sensory disturbances, such as tingling, cramps, sensations of heat and cold, pains, and girdle sensations, are common. Loss of deep sensibility, the overlying tactile sense being normal, is very characteristic. Mental disturbances may occur, sometimes of a melancholic, at others of a maniacal, form. Delusions and hallucinations are not unknown, but are rare.

It is most important to remember that the blood picture may be far removed from that which is typical of the disease if mistakes are to be avoided. This is especially so in the early stage, during remissions, and when the anaemia is very severe. Bramwell had one case in which the colour index rose in consecutive investigations from 0.8 to 2.3 during the last fortnight of life. Another case, in which the diagnosis was confirmed *post mortem* by Hurst, showed colour indices of 0.7, 0.6, 0.7, 1.2, 1.4, 1.0, 1.25, 0.8, 1.3, 1.4, and 1.0. Cases have been described in which it was continuously below 0.7, the correctness of the diagnosis having been proved by necropsies.

The earliest indication of incipient pernicious anaemia is a marked anisocytosis, with a preponderance of large oval cells, associated with achlorhydria. During certain remissions, especially those produced by liver feeding, a large number of reticulocytes are found in the blood. These reticulocytes are young red cells, rather larger than the normal red cell. Some stress is laid on these cells, because the appearance of more than 2 per cent indicates the probability of a remission, and reference will be made to them later when treatment with liver is discussed.

When the marrow is in a state of great exhaustion we may see, as in the case described at the beginning of this paper, subcutaneous haemorrhages, a feature which is very unfavourable, and often associated with a great diminution of platelets (thrombo-cytopenia).

One more event must be mentioned before leaving this side of the subject—namely, the so-called "blast crises." In these it appears as if the marrow were making a mighty effort, and pours into the blood stream almost all the varieties of cells met with there: megakaryoblasts, myeloblasts, normoblasts, myelocytes, reticulocytes, and polychromatophilic cells. As a rule a blast crisis is of very unfavourable prognostic significance, but occasionally a remission may follow.

CAUSATION

With regard to the causation of the disease little is known. Much research work has been carried out on the nitrogen, iron, fat, and carbohydrate metabolisms, but has yet no convincing results, in the way of finding a causative substance, have accrued. That it is a primary disease of the bone marrow appears most improbable. That it is due to some unknown toxin formed by microbial action on proteins in the intestine, following the loss of the antiseptic action of free hydrochloric acid in the stomach, seems much more likely. In this case the supposed toxin must be both a haemotoxin and a neurotoxin. If this be so, it is strange that feeding with large quantities of liver, which contains much protein, should be the best remedy known.

The questions must be asked: Can liver detoxicate the contents of the intestine? Is it possible that this may be a liver deficiency disease, associated with or caused by the achlorhydria? If liver feeding proves to be a curative agent, we shall want to know why, and the answer may tell us the true cause of the disease. Bile salts are found in the blood, indicating that the liver is affected in some way.

There is another disease, progressive lenticular degeneration, in which the liver is always grossly diseased, although this hepatic disease (enlipsis) has in many of the cases given rise to no symptoms during life. It has been virtually conclusively proved by Barnes that the liver disease in progressive lenticular degeneration antedates, by a long time, the nervous degeneration. Let us note that this is also a familial disease.

Manganese toxicæmia as seen in man is another nervous disease, with symptoms in many ways closely resembling those of progressive lenticular degeneration. If manganese is injected into animals it produces marked cirrhosis of the liver. Although there are no obvious hepatic symptoms in man, investigation of the liver function by levulose indicates in some of them a distinct hepatic deficiency. Treatment by liver feeding does improve patients suffering from the nervous effects of manganese poisoning, if they can be treated sufficiently early, before irrevocable damage has been done to the nervous system.

Bearing these facts in mind one cannot help wondering if the liver in health does exert some vitalizing power over the nervous system, and if the absence of this power may lead to degeneration in the nervous system.

TREATMENT

Prevention being better than cure, the question arises whether the onset of the anaemia could be prevented if all patients suffering from achlorhydria were discovered in time and treated with adequate doses of hydrochloric acid. The name of the complaint, "pernicious," is an adequate plea for the more frequent use of a stomach tube in cases which may present themselves as simple dyspepsia, and the test for free hydrochloric acid is so simple. If achlorhydria be found, years of disablement, followed by

death, may perhaps be avoided by a drachm or a drachm and a half made up into a lemonade and sipped with each meal. Perhaps liver should be given also, even in the pre-anaemic stage. Hydrochloric acid should be given permanently. Liver feeding is, however, the main treatment.

Minot and Murphy's special diet is one which is rich in proteins and food iron, especially in the liver. In addition to this they recommend fresh fruits and vegetables, while reducing carbohydrates and fats. Fats were reduced because unsaturated fatty acids are haemolytic. (Authorities, however, do not agree that there is an excess of unsaturated fatty acids in the blood in pernicious anaemia.) Following the use of this diet some very remarkable events have been noted. In a few days after its commencement reticulocytes are poured into the blood stream. Their number goes up from 1 per cent to 10 or 15 per cent, and remains so for a few days, and then gradually falls, so that the number reaches 1 per cent again in about three weeks. We saw that reticulocytes are immature red cells. This phenomenon is called "the reticulocyte hump." It appears to be a constant result of liver feeding. It does not occur in the natural remissions of the disease, or after any other known method of treatment. Liver therapy appears, therefore, to exert some very definite and specific action on the blood-forming functions of the marrow.

PERNICIOUS ANAEMIA, WITH FREE HYDROCHLORIC ACID IN GASTRIC CONTENTS DUODENAL ULCER PERFORATION OPERATION RECOVERY

BY

STANLEY DAVIDSON, B A CMB, M D, Ch B,
F R C P Ed,

ASSISTANT PHYSICIAN ROYAL INFIRMARY EDINBURGH RESEARCH
WORKER, MEDICAL RESEARCH COUNCIL BACTERIOLOGICAL
DEPARTMENT UNIVERSITY OF EDINBURGH

THE complete absence of hydrochloric acid in the gastric contents of cases of pernicious anaemia is a finding which has been so constantly reported in every country in the world that it is now recognized to be a cardinal sign of the disease. The achlorhydria, moreover, is functional, and is not the result of pre-existing gastritis, and has been found to be present in every case examined previous to the onset of symptoms. It is uninfluenced by the phases of remission or relapse or by any method of treatment. The constitutional or hereditary factor in the disease is shown not only by the facts stated above, but also from our knowledge that blood relations of cases of pernicious anaemia are often achlorhydric even when young children. The absence of hydrochloric acid automatically stops gastric digestion, as free acid is necessary for the activation of pepsin. Gastric digestion, however, is of relatively small importance, because the digestive juices of the pancreas and small intestine are ample for the purpose of breaking down the sugars, fats, and proteins of foodstuffs to the simple molecular form in which they are absorbed. On the other hand, achlorhydria is held by many workers to be of great importance in pernicious anaemia because of the resulting altered biochemical reaction of the gastrointestinal contents. Whereas the stomach and upper levels of the small intestine are, in normal individuals, practically or actually free from pathogenic bacteria, in pernicious anaemia sepsis from above and ascension of organisms from below render the gastro-duodenal flora similar to that found in the lower ileum or colon. While I am satisfied that no specific causal agent for pernicious anaemia exists, and particularly that haemolytic organisms are of no etiological importance, I feel that if the absorption of toxins, bacterial or metabolic, does not take place in these circumstances it is impossible to conceive that it ever does. Lastly, the recent work of Castle,¹ if confirmed, is worthy of consideration. He found that if beefsteak, previously digested in a normal person's stomach, is given in suitable amounts to a case of pernicious anaemia, a typical reticulocyte response could be obtained, although beefsteak itself, the gastric juices alone, or beefsteak artificially

digested, failed to do so. This would point to pernicious anaemia patients' stomachs being deficient in some property which enabled them to utilize or manufacture the specific blood hormone from animal protein.

I or the above reasons it is right that achlorhydria should be held to be a cardinal sign in pernicious anaemia, and I have consistently taught that the finding of free hydrochloric acid definitely excludes the diagnosis of pernicious anaemia. This teaching was based on bacteriological and biochemical investigation of 50 cases of pernicious anaemia before, during, and after treatment. The following case, therefore, appears to me to warrant publication.

The patient, a factory labourer aged 34 gave a history of having had influenza in 1918. In 1919 he suffered from pain in the stomach, which was diagnosed by his doctor as chronic indigestion. The pain was dull in character and constantly present. It was not relieved by or related to food. He had no vomiting. He was constipated. The attacks lasted some weeks and continued on and off for over two years when he was admitted to the Royal Infirmary, Edinburgh. After five weeks' stay in hospital his symptoms were relieved and he remained well for eighteen months.

In 1925 the pain returned and was much more severe. It was only relieved by morphine. He was admitted to Ward 31 Royal Infirmary, Edinburgh. The test meal examination showed that his free acid = 50, total acid = 66. His spleen was enlarged and he had a somewhat doughy abdomen. His condition was diagnosed as abdominal tuberculosis. He was discharged much improved, and remained well until September 13th 1926 when the abdominal pain returned and he had to stop work.

On November 13th 1926 he was again admitted to Ward 31. The pain was very sharp and was situated in the left epigastrium. It extended over the lower four left ribs. It was not related to or aggravated by food. Although mostly in front it sometimes shot through to the back, but never downwards. Sometimes it was very acute. There was no pain on micturition and no frequency, nor was it aggravated by deep respiration or straining at stool. There was no vomiting, sweating, or diarrhoea but the patient had periods of constipation.

Asked as to previous illnesses he stated that he had had measles and influenza. His general surroundings were good, but his work which was moderately hard was done in a bad atmosphere. He was a moderate smoker and nearly a total abstainer from alcohol.

Family History.—Mother and father both alive and well two brothers aged respectively 35 and 19 were alive and well one brother and one sister died in infancy. There was no similar disease and no tuberculosis in the family.

State on Examination.—He was 5 feet 4 inches in height and weighed 8 st 4 lb, he was of average intelligence and was poorly developed and thin (temperature 97° F). He stated that his appetite had been poor for years. He often had a feeling of weight after food, but consistently denied that food aggravated or alleviated the pain. There were no cruetations, acidity or heartburn. His teeth had all been extracted six weeks previously.

Inspection of the abdomen showed it to be rather scaphoid. There was no local prominence or retraction. On palpation no tenderness or rigidity of muscle was elicited. There was a suggestion of a doughy feeling on splashing. The liver was not enlarged. The spleen was enlarged and palpable two inches below the costal margin in the mid axillary line, it was not tender and there was no friction on auscultation.

A test meal given on November 16th showed free acid = 23, total acidity = 50.

X Ray Report.—J shaped stomach of good tone and peristalsis. Duodenal cap persistently deformed and tender. At end of six hours the head of the meal had reached the hepatic flexure. The stomach was again filled and the deformity was again seen. At the end of twenty four hours the whole of the colon was outlined which is evidence of marked spasticity. Conclusion. The x ray examination is very suggestive of duodenal ulcer.

Haematopoietic System.—A blood count on November 16th 1926 showed red blood cells 2 640 000 per cmm, white cells 11 000 per cmm, haemoglobin 76 per cent, colour index 1.04.

A detailed report on the nervous, urinary, circulatory, and respiratory systems is given in the case history but as nothing abnormal was found it is unnecessary to repeat the information.

On November 21st 1926 the patient suddenly got an acute pain in the right epigastrium, accompanied by profuse sweating and board like rigidity of the abdominal muscles. The condition was diagnosed as a perforated duodenal ulcer and the patient was transferred to the surgical side for operation. The following day at 1 a.m., Mr. Hingworth operated. He found greenish fluid exuding from a perforation in the anterior wall of the duodenum. The stomach, gall bladder, liver and appendix were perfectly normal. The spleen was enlarged. A posterior gastro-enterostomy was performed and the patient made a perfect recovery.

On July 23rd 1928 the patient was admitted to Ward 32 complaining of weakness and loss of weight and pain in the back and right epigastric region which was not aggravated or relieved by food. On examination I confirmed the past findings and history as stated above. The patient was thin and emaciated and weighed only 6 st 13 lb. His skin was yellowish, suggesting slight jaundice. It in no way resembled the lemon yellow tinge so typical of pernicious anaemia. He was obviously anaemic and suffered from breathlessness on exertion and had soft systolic murmurs over the mitral and pulmonary valves. Apart from palpation of the spleen two inches below the costal margin, there

was nothing to be made out in any system except as stated below.

Alimentary System—Barium outlined a small high stomach from which the food was leaving rapidly through the gastro-enterostomy opening, which appeared well formed and oval which there was no tenderness. No barium was leaving by the pylorus, but no filling defect of distal portion of the stomach could be made out which might suggest new growth. *Six hours* Residual flakes of barium round stroma. Stomach was refilled and previous examination confirmed. No evidence of a gastric lesion was found. (Report from Radiological Department.)

Haematopoietic System—No enlargement of glands anywhere. A blood count taken on July 25th showed red blood cells 1 320 000 per c mm white cells 7 000 per c mm, haemoglobin 32 per cent, colour index 1.2. This was confirmed on July 26th and on August 4th, except that on the latter date his white blood cells numbered 10 000 per c mm. The blood picture showed marked megalocytosis and anisocytosis and was absolutely typical of pernicious anaemia except for the absence of leucopenia. The white blood cells varied from 7 000 to 10 000 per c mm on different occasions 80 per cent of which were polymorphonuclear leucocytes. Except when there has been concomitant disease of the kidneys, I have never found a white count so high as this in any case of pernicious anaemia. The fragility test was normal. The van den Bergh test showed direct reaction—weak delayed reaction indirect reaction—positive reaction. This was indicative of haemolytic (non-obstructive) jaundice. The Wassermann reaction was negative.

Test Meals—Three test meals were given at different times. The first two showed no free hydrochloric acid. This was not surprising since the fluid tested was a greenish bile-stained mixture of gastric and duodenal contents. The third test made just previous to discharge from hospital consisted mainly of stomach contents which turned red litmus blue Congo red blue and gave a positive Gunzberg reaction. Titration showed free acidity=25 total acidity=51.

Treatment

The patient was placed on light diet and given alkalis and liver by the mouth. Following this treatment the gastric pain disappeared and the patient put on weight rapidly. He gained 1½ st in six weeks. The symptoms and signs of anaemia quickly disappeared and his blood count rose from 1 350 000 red cells per c mm and haemoglobin 28 per cent on August 4th to 3 690 000 red cells per c mm and haemoglobin 60 per cent on August 27th. The white blood corpuscles remained at 8 000 per c mm. A typical reticulocyte rise occurred and the response to treatment was exactly what one is accustomed to get in a case of pernicious anaemia but not in secondary anaemias. The enlarged spleen remained unchanged.

The patient was discharged from hospital looking and feeling very well.

Summary

It is interesting to obtain a long history of epigastric pain which the patient consistently denies is affected by the taking of food, and yet find he is suffering from duodenal ulcer. The presence of marked megalocytosis and anisocytosis, a colour index over unity, and a van den Bergh reaction characteristic of haemolytic jaundice, are all classical signs of pernicious anaemia. On the other hand, the presence of free hydrochloric acid in the stomach and the absence of leucopenia contraindicate the diagnosis. Moreover, there is considerable evidence to show that pernicious anaemia patients conform to a constitutional type or build. Thus Addison noted that the disease occurred chiefly in persons of a somewhat large and bulky frame. More recently Diaper,¹ by his laborious method of anthropological measurements of 45 cases, confirmed this observation, and showed that the pernicious anaemia group tended in their measurements very decidedly to approach the aeromegalic. My own clinical experience agrees with these views. My first visual impression of the patient described in this paper was of a small, badly developed, emaciated, haggard man, who was probably suffering from a simple or malignant ulcer of the stomach. Without many blood examinations I would have been loath to diagnose the case as pernicious anaemia.

Hurst and Haintman² have reported pernicious anaemia occurring after gastrectomy in a very few cases. Conybeare³ has reported a case following gastro-enterostomy.

In the case reported here the blood condition was present previous to operation and so far as I am aware, the co-existence of duodenal ulcer and pernicious anaemia in a patient has never previously been reported.

I have to thank Professor Edwin Bramwell for the early notes of this case during the patient's stay in his ward and Dr Alexander Goodall for his assistance and his permission to publish the case.

CHRONIC NEPHRITIS IN CHILDHOOD *

BY

J C SPLACE, M.D.,

Honorary Assistant Physician and Chemical Pathologist,
Royal Victoria Infirmary, Newcastle-upon Tyne

From the standpoint of morbid anatomy there are no forms of chronic nephritis which are peculiar to childhood, and conversely, even an arterio-sclerotic granular kidney may occasionally be found in children. There are, however, certain clinical features about the disease in children which deserve attention. So in this discussion it will be profitable both to describe our experiences of the various forms of the disease in children and also to consider if there be anything peculiar or characteristic about them in childhood which will throw light on some of the obscure problems of the subject. It is in this light that the study of disease in childhood may be looked upon as an important branch of comparative medicine, and as such should concern us no less than the study of actual "children's diseases," of which, *sensu stricto*, there are very few examples.

For the convenience of description and discussion a classification of the various forms of chronic nephritis must be attempted. It is usual to deplore the fact that the various clinical types of the disease are difficult to correlate with the classifications given to us by the morbid anatomists, but I think that we can agree that there are at least three groups of the condition which occur in childhood and that in the main they are widely different and best considered as separate diseases. These are (a) chronic interstitial nephritis, (b) chronic parenchymatous nephritis, including nephrosis, and (c) chronic ascending pyelonephritis.

It is probable that each of these three groups can be further differentiated into types which in themselves are distinct diseases, but for the present they will serve our purpose, being clinical entities which we are accustomed to recognize and content to diagnose.

I have purposely included chronic ascending pyelonephritis for discussion. Truly it is not a primary disease of the kidney, but the same may perhaps be said of nephrosis, and it has this clinical importance, that it may impair the renal function in the same way as chronic interstitial nephritis, and so is likely to be mistaken for it. Moreover, it deserves some comment, for occasionally the ascending infection is due to an obstruction of the urinary tract which can be treated successfully, thus is more than can be said for most other forms of chronic nephritis.

My classification does not include two conditions which are sometimes spoken of as forms of chronic nephritis—namely, chronic haemorrhagic nephritis, and a syndrome to which Heubner gave the name "paedo-nephritis." The first of these is characterized by attacks of haematuria without oedema, which usually follow throat infections. I am inclined to look upon them as examples of recurrent attacks of slight acute glomerular nephritis. It is true that some of these cases do ultimately develop chronic interstitial nephritis with hypertension, but I know of at least two cases which have suffered from these attacks for more than ten years, and so far there has been no impairment of general health or of the renal function. "Paedo-nephritis" is a term which could now be discarded. Heubner coined it thirty years ago to describe doubtful forms of chronic nephritis in children who showed no other signs than albuminuria and anaemia. It is probably no distinct entity, but includes conditions such as latent chronic nephritis, toxic albuminuria, and orthostatic albuminuria.

CHRONIC INTERSTITIAL NEPHRITIS

It is this form of chronic nephritis in childhood which will yield some of the most interesting points for discussion. At one time it was considered a great clinical rarity, and in 1896 Leonard Guthrie, while writing a wonderful description of its signs and symptoms, was able to collect from the literature only seven cases under the age of 14. By 1903 Sawyer was able to collect twenty-four cases. But

* Read in opening a discussion in the Section of Diseases of Children of the Annual Meeting of the British Medical Association Cardiff 1928.

still the subject attracted no great attention apart from the possibility of its being a result of congenital syphilis, a view widely held at that time. In 1911, however, Morley Fletcher, Parsons, and Miller drew attention to the fact that the disease might result in peculiar bony changes and dwarfism and since that time a great number of cases have been recognized. More recently biochemical methods of examination have added further interest giving us clearer means of diagnosis.

Now of this disease, which we call *chronic interstitial nephritis*, I believe that we can recognize three clinical types in children in whom they are more easily distinguishable than they are in adults. Each of these types has probably its own mode of origin and evolution as a separate disease, although proof of this may be lacking when we attempt it by examining the end results in the kidneys after these diseases have run their course.

Taking them first as a group it will suffice briefly to mention some of the common clinical features and their variations which are found during the

FIG. 1—Renal dwarfism in a girl aged 10.

course of the disease. The symptoms may arise at any age from infancy onwards and usually advice is not sought for several years by which time a history of thirst, polyuria, anaemia, and arrested development can be obtained. On the other hand, an attack of uraemia, of one sort or another, may be the first warning of the disease.

In the majority of cases there is no history of an initial renal nephritis or of any illness which would be likely to cause it. On the other hand, in the minority the disease can be traced to an attack of acute nephritis or more commonly to a preceding illness of prolonged sepsis, and I think that it is on this point that two of the types I shall mention can be distinguished.

In the well-established cases the patients are usually emaciated, with coarse, dry, and pigmented skins. The general health is poor and they are liable to recurrent attacks of uraemic vomiting and headache. There is no mental defect, indeed, the patients seem to be shrewd, precocious and intelligent beyond their years. One of my patients at the age of 6 was a regular performer on the music hall stage as an infant prodigy at the piano. To the eye he looked no more than the age of 2 as he sat singing in a high shrill voice to his own accompaniment. To describe such cases, Guthrie quoted W. S. Gilbert's precocious child "who died an enfeebled old dotard at five."

When the dwarfism and bony changes are present they may be extreme, as will be seen from the accompanying illustrations (Figs 1 and 2). Fractures are common, and the gait becomes slow and uncertain. These bony changes are not likely to appear in those cases which run a rapid course towards their terminal uraemia. In studying the disease the bone deformities are of great clinical importance since they give us a valuable means of assessing the duration of the nephritis. They do not occur unless renal function is much impaired, so, for example, if a child with chronic nephritis has had bone deformities and failed to grow for ten years we can presume that he has been sorely afflicted with the disease for at least ten years.

Polyuria is one of the most prominent symptoms, and in one of my cases it was for this that advice was sought by the mother who remarked, "He passes urine night and day just like tap water." The amount of albumin is variable, and may be so slight at times as to be easily overlooked. Casts, leucocytes, and red cells are to be found in the urine as in the chronic nephritis of adults. The blood pressure may be normal throughout, high throughout or become high in the course of the disease. This is an important point, to which I shall refer again in classifying the different types.

Renal retinitis may be absent throughout, even though the patient die in uraemia. In my experience it is present only in those cases with high blood pressure. The renal function tests will demonstrate great loss of function in all cases of "renal dwarfism" and "renal rickets." In these the blood urea lies usually between 50 and 100 mg per 100 c.c. of blood, rising beyond that with each attack of uraemia.

It is on certain combinations of these various symptoms and signs that I would propose to subdivide the cases of chronic interstitial nephritis into the three following types.

TYPE I—*Chronic Interstitial Nephritis—Primary Renal Type without History of Acute Nephritis or Preceding Sepsis*

(Chief features: Unrecognizable onset, marked azotaemic nephritis, slow course with renal dwarfism developing, normal blood pressure, no retinitis, true uraemia. Small white kidneys at necropsy.)

These are the cases which start insidiously without any preceding acute nephritis, oedema, or prolonged septic illness. They are usually first seen when dwarfism or bone deformities are developed. By this time the blood urea is already high, and they present all the symptoms of the "syndrome de retention azotée" of Vidal and Javal—dry skinned and shrunken, with foul breath, stomatitis, subnormal temperature, and evident uraemic digestive symptoms. In the majority the blood pressure remains normal to the end, or, if raised, is rarely above 150 mm. and no retinitis appears. Attacks of tetanus, though not common, may occur with this type. The terminal uraemia is of the sort best described as true azotaemic uraemia, an undramatic picture of muscular twitchings, vomiting, and coma. There may be a terminal convulsion, but striking cerebral phenomena such as transient amaurosis or monoplegia do not occur. It is the type of uraemia which we see with calcareous auria in adults, and I am inclined to think this is the picture of true uraemia when uncomplicated by hypertension—although the textbooks call it "latent uraemia," because it lacks certain dramatic features. The following typical case illustrates this type.

J. S. (see Fig. 2) was under close observation from the age of 15 to 18 when he died in uraemia. He had been in chronic ill health from the age of 4, with maldevelopment of the bones and severe rickets. Prior to that he had not thrived well. In infancy he had measles and chicken pox. There was no history of scarlet fever of skin sepsis or of oedema. At the age of 8 an osteotomy was performed for the correction of his deformities and again about the age of 10. At the age of 15 he was found to have albumin in his urine and he then came under my care. At this time a history of polyuria and thirst since the age of 4 was elicited.

On examination he was found to be 18 inches below the normal height for his age. There was marked genu valgum and active rachitic changes at the radial epiphyses. Albumin and casts were in the urine. Blood urea was 59 mg per cent and the highest urea concentration in the urine was 0.90 per cent. The systolic blood pressure was 105 mm. and the optic discs and retinae were normal. There was no enlargement of the heart. During the next three years he led the life of an invalid scarcely able to walk about. His blood urea was constantly raised, and varied from 52 to 341 mg per cent. He had several attacks of tetany during this time. His blood phosphorus varied from 4.1 to 12 mg. and his serum calcium from 10.4 to 6.2 mg per cent. He died in a uraemic attack of thirty-six hours duration which was ushered in by vomiting and muscular twitchings and ended in coma. During the whole of the time he was under observation his blood pressure remained below 110 mm., and renal retinitis did not appear although frequent examinations were made up to the hour of his death. At the post mortem examination both kidneys were small (right 19 grams, left 25 grams). The capsule was not thickened and stripped fairly readily. After examination they were described

FIG. 2—Renal dwarfism in a lad aged 18, with chronic interstitial nephritis.

"Both kidneys have an embryonic appearance although the changes are those of chronic interstitial nephritis." The heart was not enlarged.

This is a typical example of renal dwarfism due to chronic interstitial nephritis of this type. It is reasonable to presume that he had suffered from it for at least fourteen years, yet during this time there was no rise in blood pressure. During recent years I have had five other similar cases under observation. Four of these are already dead in uraemia. The highest systolic blood pressures in these have been 95 (age 6), 100 (age 4), 100 (age 10), 105 (age 7), 160 (age 12). In none of these could I obtain a history of preceding acute nephritis or sepsis.

The type of kidneys which are found on *post-mortem* examination in these cases is always the same—small, pale, and shrunken, weighing usually about 1 oz. The capsule strips fairly readily, and in cortex are often to be found small nodular areas of local hypertrophy of kidney tissue. They are "small white kidneys."

TYPE 2—Chronic Interstitial Nephritis—Primary Renal Type with a History of Acute Glomerular Nephritis or Prolonged Sepsis

(Chief features. Within a few years of the initial illness high blood pressure (150 to 200 mm.) cardiac hypertrophy, albuminuria, numbers of red cells in urine, retinitis, the course of the disease is usually rapid. Dwarfism and rickets may develop.)

It is well recognized that transient tonsillar sepsis from streptococcal infection is a cause of acute glomerular nephritis. Other forms of sepsis are equally important, and in my own series of cases I have found that skin sepsis, whitlows, and gland abscesses are more common causes than tonsillar sepsis.

It is true that the majority of these cases of acute nephritis are cured completely, but on a *priori* grounds it is reasonable to presume that when the kidney damage has resulted from sepsis of a more prolonged character, such as might occur in cellulitis and osteitis, a chronic nephritis would be more likely to ensue. This is in accord with my experience of certain cases of severe chronic nephritis in young adults, with blood pressures of about 180 to 200 mm., albuminuria, red cells in the urine, and azotaemia. In many of these I have been able to obtain a history of cellulitis or "blood poisoning" a year or two before the first serious symptoms of chronic nephritis. Very often there has been no evident oedema or gross haematuria in the early stages to draw attention to the kidneys and to invite a close examination of the urine, and the presence of red blood cells in the urine—which is the chief and most important sign of acute glomerular nephritis—may have been overlooked. The following is an example of a case of this type in a child.

A schoolboy, aged 10, was admitted to hospital with appendix abscess. Prior to that he had been in perfect health without any history of previous illnesses. The abscess was drained, but was followed by a period of extreme illness for four weeks with high swinging temperature. At this stage an empyema was diagnosed and rib resection was performed with the evacuation of a quantity of thin pus. For two weeks afterwards the patient was in a critical condition with septic fever which slowly subsided. Convalescence was prolonged and it was six months before recovery was complete enough to allow him out of bed. Then followed a period of two years in apparent good health. The next striking symptom was a complaint of slight visual impairment believed to be an error of refraction for which advice was sought from an ophthalmological surgeon. Examination revealed a retinal haemorrhage.

On examination at this stage the urine was found to contain a large quantity of albumin, casts and some red cells, and the blood pressure was 195 mm. The heart was enlarged. Urine urea concentration was 14 per cent, and blood urea 92 mg per 100 c.cm. of blood. After this the course of the disease was rapid. Headaches were a prominent symptom and he died eight months later after a "uraemic phase" which lasted off and on for three weeks. In this uraemia headache, restlessness and convulsions were the most prominent features. Towards the end some oedema over the sacrum appeared.

This is a clinical example of a malignant type of chronic interstitial nephritis not common among children, but fairly frequent in early adult life.

TYPE 3—Chronic Interstitial Nephritis—Primary Arterio-sclerotic Type with Secondary Contraction of the Kidneys

(Chief features. A preliminary stage of high blood pressure—often over 200 mm. at first examination—cardiac hypertrophy, retinitis, tendency to uraemia of cerebral type, with transient amaurosis, monoplegia and convulsions. Later albuminuria and some azotaemia develop. Death from heart failure or apoplexy.)

It is not uncommon to see a young adult with a blood pressure over 200 mm., with a normal blood urea, with kidneys capable of concentrating efficiently, and with a mere trace of albumin in the urine. He is subject to headaches, but is capable of work. In this state he may continue for a few years with the blood pressure slowly rising. I know of such a case—a bricklayer, who had been working on scaffolding with a blood pressure of 305 mm. Sooner or later the albuminuria becomes severe and constant, and death takes place in apoplexy or as a result of heart failure. So long as there is no gross albuminuria these patients have a fair chance of survival, but when it appears their term of life is short. The primary disease in this condition is that form of arterio-sclerosis which Gull and Sutton named "arterio-capillary fibrosis," and which Evans and others name "diffuse hyperplastic sclerosis." The patients usually live long enough for the kidneys to become small and contracted, and after death they are commonly called granular kidneys or small red kidneys.

These are well-known clinical facts, which I mention only to ask if this arterio-sclerotic disease, primary diffuse hyperplastic sclerosis, is recognizable in a young child apart from severe chronic interstitial nephritis or at a stage before the kidneys become affected. It appears to be extremely rare. Evans' in his article on "Arterio-sclerosis in children" quotes a case (No. 2) of a boy who, at the age of 7, had a blood pressure of 195, with a trace of protein (0.001 per cent) in the urine, which gave all the reactions of globulin. Seven years later he had a blood pressure of 265 mm. systolic, 200 mm. diastolic, with a blood urea of 67 mg per 100 c.cm. and 0.025 per cent of albumin in the urine. He died of cerebral haemorrhage, the kidneys showing advanced chronic nephritis. But in this case there was evident dwarfism at the age of 7 with genu valgum, so it is probable that he had chronic nephritis already at that stage.

From my own experience I can quote the following case, of a child with high blood pressure and normal renal function who had an attack which was thought to be uraemia, which appears to be a true example of the type mentioned.

A girl, aged 10, was admitted to hospital with a history of generalized convulsions and some mental disturbance in which she was restless and noisy. On admission she was thought to be suffering from encephalitis. She was well nourished and of normal stature. The next morning the mental condition was clearer but there was complete amaurosis and palsy of the left arm. There was no muscular twitching and no vomiting. The retinæ showed some haemorrhages but no papilloedema. The aortic second sound was very loud and when the blood pressure was taken it was found to be 220 mm. systolic. The urine contained a trace of albumin but no deposit. The cerebro-spinal fluid was clear without pleocytosis. In two or three days the amaurosis and the monoplegia disappeared and no more convulsions occurred. This was looked upon as a case of uraemia because of the symptoms, blood pressure, retinitis and albuminuria. When, however, the blood urea was examined it was found to be only 26 mg per 100 c.cm. and urea concentration was normal. The child passed on towards recovery. Seen two years later there was commencing deterioration of renal function. Albumin was more evident, the blood urea was 45 mg per 100 c.cm., renal retinitis was again present, and the blood pressure was 210 mm.

The chief importance of such a case as this is the light it throws on what is called uraemia. Here we have a child with normal renal function showing such classical uraemic manifestations as transient amaurosis and monoplegia, whereas in the first type I have described, where a typical severe interstitial nephritis is combined with extreme impairment of renal function and azotaemia, the chief symptoms are vomiting and muscular twitchings. The former is, I think, a mere cerebral vascular syndrome, due to hypertension, and it is the latter which is true uraemia. In the second clinical type I described, in which high blood pressure and severe renal damage advance together, the uraemic picture is likely to be a confusion of the cerebral vascular syndrome with true uraemia, and it is that which is most frequently seen in adults.

I would like to stress the fact that these three types of chronic interstitial nephritis are merely a convenient clinical subdivision of the cases. They may suggest, but do not explain, the association of chronic nephritis and arterio-sclerosis, or other problems of pathology. Evans' studies have led him to the conclusion that the form of arterio-sclerosis we have been discussing is an inflammatory and not a degenerative lesion. If that be so, these three types may be different manifestations of the same disease,

in which the variation depends on the site of the damage—the kidney alone in the first type, the systemic vessels in the third type.

Etiology of Chronic Interstitial Nephritis

It is the cases of the first type I have described—slowly advancing azotaemic nephritis with little or no rise in blood pressure—which are commonest in children. In many of these the history suggests that the symptoms of the disease started in the first year of life. Kitcher, when discussing his original case, was of the opinion that the disease dated from intrauterine existence, and many others have supported a view of some congenital infection. This is probably not true in all instances, however. Barber's² cases occurred mainly in adolescence, and Rose Bradford³ has described young adults who die in uraemia with small white kidneys without cardiac hypertrophy or arterio-sclerosis (aplastic Bright's disease some people called them in those days), which is probably the same condition. Both sexes are equally affected (26 males and 25 females in a series collected by Hunt⁴), and there is no recognizable familial tendency. Syphilis can now be ruled out as a cause. In more than 90 per cent of cases there is no evidence of infection of mother or child. It must be concluded that we know nothing positive of the etiology of these cases.

In the second type of case I have described I have already suggested that a severe septic illness, even though it produced no recognizable acute nephritis, may be the cause.

In the third type the cause of the arterio-sclerosis is unknown, but it must be borne in mind that it is probably an inflammatory and not a degenerative agent.

Renal Dwarfism and Tetany in Chronic Nephritis

When a chronic interstitial nephritis has existed for some years, bone growth and development are usually affected. The changes in the bones have been fully described by Parsons,⁵ Paterson,⁶ and others, and are commonly spoken of as "renal rickets" or "renal dwarfism." They are the result of a metabolic disturbance which accompanies azotaemic nephritis, but they do not yield to the usual antirachitic remedies. Indeed, it occurred that one of my cases was thrown into uraemia after exposure to ultraviolet ray treatment. X-ray and histological examinations have shown that the changes are as follows: (a) actual cessation of growth and development at the epiphyseal line, producing dwarfism; (b) a rachitic change at the epiphyseal line, best seen at the lower end of the radius; (c) atrophy and osteoporosis of the shafts of the bones. One or other, or a combination of these, is to be found in most cases, and clinically they may present themselves as examples of late rickets or, as in Barber's cases, of adolescent genu valgum. If the course is prolonged there may be periods of temporary improvement with a healing line, which can be seen in a radiograph of the epiphyses as a narrow dense stratum. It must be mentioned that in some cases of short duration the bones remain quite normal.

Frank tetany is not a common symptom. As far as I know it has not been recorded in any of the published cases, but in two of my own it was a prominent feature. In many cases, however, latent tetany can be shown to be present by Chvostek's sign, and this should be sought for whenever chronic interstitial nephritis is suspected.

The changes in the calcium and phosphorus content of the blood throw some light both on the bony changes and the tetany. From the work of Greenwald,⁷ de Wesselow,⁸ and others it is known that in the azotaemic form of nephritis there is a retention of phosphorus, which may rise from its normal level of 3 or 4 mg to 15 or 20 mg per cent in uraemic cases. With or as a result of this, there is often a corresponding fall of calcium in the blood. I have been able to confirm this in some of my own cases of chronic interstitial nephritis with renal dwarfism, but in others there has been a rise of blood phosphorus only, without any fall in blood calcium. When one considers that ordinary infantile rickets is associated with a diminished amount of phosphorus in the blood, and tetany with a diminished amount of calcium, it is reasonable to believe that the bony changes and the tetany which may be present in chronic interstitial nephritis are also dependent on a disturbance of the phosphorus-calcium ratio of the blood and tissue fluids. On this point Parsons has advanced an interesting theory, which some of you may wish to comment

on. Speaking of those cases which have a high blood phosphorus but normal blood calcium, he says:

It seems conceivable that the serum calcium is maintained at this level to prevent the occurrence of tetany which is such a very serious complication and to which the young and growing child is much more prone than the adult. It is therefore not improbable that in renal rickets there is a washing out of calcium from the bones with resulting osteoporosis and rickets.

If Parsons's suggestion be correct, it is probable that the parathyroids would be the organs concerned in producing this effect. Now this may explain cases of parathyroid hypoplasia in chronic renal disease described by Bergstrand,⁹ Thomas, and Wentworth,¹⁰ which Box and de Wesselow¹¹ refer to in their published case of chronic nephritis with a possible parathyroid syndrome.

Renal Retinitis and Blood Pressure

In all the cases which I have seen of chronic interstitial nephritis in children with normal or low blood pressures no retinitis has been observed, even during or after their attacks of uraemia. To confirm this experience I have looked over 29 published cases in which the blood pressure was recorded. In 21 of these it was normal, in one 130 mm, in one 138 mm, in one 165 mm, and in 4 over 200 mm. The state of the retinae and discs was mentioned in 15 of these. They were normal in 9 cases, which all had blood pressures below 150 mm, and renal retinitis was present in 5 cases, in which the systolic pressures were 260, 250, 210, 165, and 100 mm. The remaining case had primary optic atrophy but no retinitis. Thus I could find only one case of chronic interstitial nephritis (Glaser¹²) in which retinitis was present with a normal blood pressure of 100 mm, and that child was dying of acute diphtheria at the time. From this I would conclude that so-called albuminuric or renal retinitis in children is not a manifestation of albuminuria or uraemia, but of hypertension or vascular disease, a view that has long been held by many.

Treatment

The treatment of chronic interstitial nephritis in children leaves little scope for discussion. It is well to bear in mind that some of the reported cases have died in uraemia immediately after an operation for the correction of the deformities. The best that can be done is to preserve what health they have by conservative methods. No success has been achieved by the use of glandular extracts.

CHRONIC PARENCHYMATOUS NEPHRITIS OR NEPHROSIS

This is the commonest form of chronic nephritis in childhood, and, taking year for year, it is more prevalent among children than among adults. In a series of 23 cases reported by Clausen,¹³ 15 were below the age of 7 years and 8 between the ages of 8 and 15, and this can be taken as a fairly typical age distribution.

Whether we call the disease "chronic parenchymatous nephritis" or "nephrosis" matters little. Müller¹⁴ coined and uttered the latter term in 1905, maintaining that the lesion of the kidney was a degeneration and not an inflammation. An opposite school of pathologists replied that that type of degeneration was the result of an inflammation, and refused to accept the term. Now it appears that the disease is not primarily a disease of the kidney at all, but a general disease with "an abnormal permeability of the cutaneous and renal vessels for albumins and lipids referable to changes of metabolism", so the most recent fashion is to call it "lipoid dystrophy of the kidneys." A fairly clear conception of the malady can be obtained if we use the word "nephrosis," and look upon it as a general disorder in which the kidneys are large and pale with tubular degeneration, and recognize that in this state the kidneys may be further damaged by a superimposed infection which produces an actual nephritis and complicates the picture.

Clinically there are certain clear features of the disease by which we may recognize it: obstinate oedema with effusions into the serous cavities, marked albuminuria, absence of haematuria, normal blood pressure, normal renal function, increase of cholesterol in the blood, diminution of the plasma proteins, and a peculiar susceptibility to secondary infections, especially to pneumococcal peritonitis.

The only evidence that the clinical condition is due to a disease of the kidneys is the albuminuria and the casts in the urine. Marriott¹⁵ refers to cases in which the oedema preceded the albuminuria and the appearance

of casts. If this is so, there are good grounds for the belief that it is not primarily a kidney disease, but that the kidney becomes large and white with tubular degeneration, as do other tissues in the body. By some it is held that the oedema is due to the retention of chlorides by a diseased kidney, but de Wesselow¹³ has shown that the absence of chlorides from the urine is not due to this. The kidneys are quite capable of passing and concentrating chlorides, but they do not get the opportunity, for chlorides are retained in the tissue fluids for other reasons.

Without going further into the definition and description of the disease and its pathology, there are certain practical clinical problems which may be considered for discussion. The first of these concerns the diagnosis. Can it be taken for granted that an absence of red cells from the urine and a normal blood men are essential before making a diagnosis? I do not think so myself, but I agree with the view that in a classical uncomplicated case there are no red blood cells in the urine, and the blood urea is normal, and that this is sufficient evidence that there is no inflammatory lesion at least in the glomeruli. Rarely, however, do cases run an uncomplicated course. They are peculiarly liable to secondary infections, and at such times a glomerulitis with haematuria and mitogen retention is superimposed. Under, Maxwell, and Green¹⁴ have given a very excellent description of prolonged observation of a patient who had intermittent periods of mitogen retention and died ultimately with bronchopneumonia, when the non-protein nitrogen of the blood was 187 mg per cent. On the other hand, I had the rare opportunity last year of following a case in a young child in whom the disease ran its course, while the blood urea was normal and there were no red cells in the urine. A very careful histological examination showed that there were no glomerular lesions and no red cells in the tubules—only marked tubular degeneration with the typical lipid substance present.

The next point concerns treatment. Marriott, a great authority on the disease, is a strong advocate of the view that it is due to a toxin which damages the tissue cells, and causes them to absorb more chloride from the blood, so producing oedema. The toxin is usually from a staphylococcal infection of the mastoid or paranasal sinuses. He advises a very thorough examination and exploration of these sites, and reports cases of rapid cure after drainage by operation. Is this a view with which most of us agree, and if we do not agree with it, is it because we have failed to recognize the local staphylococcal infections in our cases? Another form of treatment which Osman¹⁵ has revived is the use of large doses of alkali. On occasions its use is followed by the disappearance of oedema, but the same can be said for almost any other form of treatment. It should be tried in obstinate cases, but it is to be remembered that it often produces severe vomiting and tetany.

It is difficult to assess the value of any form of treatment for the disease is liable to incalculable fluctuations, and spontaneous cure may take place. Some of the most remarkable cases of cure are those in which the symptoms have disappeared after the patient has weathered the storm of an acute intercurrent illness such as influenzal pneumonia. There are other points in treatment on which it is easier to agree—namely, that a high protein diet is beneficial, that decapsulation of the kidney is useless and that it is imperative that every patient with nephrosis should be guarded rigidly against the danger of intercurrent infections in case he develops an acute lesion in the glomeruli and haemorrhagic nephritis.

The prognosis is a matter on which it would be useful to collate our experiences. Of Clausen's 23 cases in children, 10 died, 9 of infection and one of alkalosis due to an overdose of sodium bicarbonate. Of Schwarz and Kohn's¹⁶ 17 cases, 6 died and none of the others can be declared well. My impression is that although the oedema may disappear, albuminuria and ill health remain, for such was the result in 5 patients I have been able to trace who have survived for more than three years. I would like to ask if anyone can record cases of nephrosis which, after an initial stage of oedema lasting more than ten weeks have been cured and remained in permanent good health free from oedema and albuminuria.

CHRONIC ASCENDING PYELONEPHRITIS

Urinary infections are so common in infancy and early childhood that it is appropriate to consider what chronic renal damage may result therefrom, and whether some of the unexplained types of chronic interstitial nephritis do not have their origin in an ascending infection.

Most cases of acute pyelitis, if promptly diagnosed and treated, make a satisfactory recovery. There are others, more chronic, which remain in ill health and liable to recurrences of fever and pyuria. In a few of these a permanent damage to the kidneys ensues, and the failure in renal function shows itself as an advancing azotaemic nephritis ending in uraemia. If the condition is sufficiently prolonged, these patients become chronic invalids and develop renal dwarfism, and to all appearances look like the stunted dry skinned child with the primary renal type of chronic interstitial nephritis. In such circumstances it should be asked if there is not some chronic obstruction or deformity of the urinary tract which is the cause of the infection, for in children, as in adults, imperfect urinary drainage plays an important role in this.

One of the most striking examples of ascending pyelonephritis is due to the valvular obstruction in the posterior urethra of male children described so well by Young, Piontz, and Baldwin.¹⁷ This is a valvular obstruction amenable to surgical treatment, but if neglected it leads to hypertrophy of the bladder, dilatation of the ureters, pyonephrosis, and uraemia.

A review of the literature of the subject prior to 1919 shows that there had been reported only two cases of valvular urethral obstruction in which a diagnosis had been made during life. Since then a large number of cases have been recognized and successfully treated. In Hugh Young's clinic at Johns Hopkins Hospital, 12 such cases were seen in six years. In this country a case has been recently treated and reported by Gilmour.¹⁸ In one case which I have seen, a small boy in a chronic uraemic state was apparently cured and completely restored to health by operation.

I have mentioned briefly this type of case merely to invite attention to the possibility of the condition as a cause of chronic renal disease. It should at least be considered in every case of chronic pyelitis and uraemia in a young boy. When the subject is looked at conversely, however, there are few of the cases of chronic nephritis or renal dwarfism which can be traced back to an acute or chronic pyelitis.

I have attempted the task of describing and suggesting certain aspects of chronic nephritis in childhood which lend themselves to discussion, but I realize how truly Müller spoke when, in the address in which he introduced the term "nephrosis," he described the kidney as "ein heimtückisches Organ." For I also have found its diseases too spiteful satisfactorily to be described and confined within the limits of this address. But from a study of these diseases in children there emerge two significant facts to which I would direct your particular attention. (1) the "small white kidney" is the commonest form of chronic interstitial nephritis in children, and it does not appear to result from any preceding acute nephritis or infection, and (2) this disease, though resulting in uraemia, does not produce any rise in blood pressure or retinitis.

SPLENOMEGALIC POLYCYTHAEMIA WITH HIGH BLOOD PRESSURE

BY
I. PARKES WEBER, M.D. FRANCIS F. BARKER, M.D., C.M.
I.R.C.P.,
1. SHIRLEY ADAMS, M.D., M.R.C.S.,
AND
W. F. CARNEGIE DICKSON, M.D., B.Sc., I.R.C.P.

It has been maintained by one of us (F. P. W.) that, contrary to what one would formerly have expected in true cases of splenomegalic polycythaemia (Vaquez-Osler disease), or erythraemia, the blood pressure is generally not or not much above the average, in spite of the excessive so-called 'blood viscosity'—in fact, that the presence of excessive blood pressure would suggest that any case in question is either not a true one of erythraemia or that it is complicated with contracted kidney or arterio-sclerosis (especially of the medulla oblongata, as a cause of arterial hyperpiesia)*. The following case bears on this and some other questions.

The patient, a single woman aged 53 years, returned from Switzerland in the early summer of 1927 complaining of violent indigestion, neuralgia in the eyes, cardiac palpitation and slight irregular loss of blood per vaginam. A Swiss oculist had examined the eyes and pronounced them normal. An abdominal swelling, evidently an enlarged spleen, was discovered. It was rather hard and reached down to below the umbilical level. A radiogram showed the greater curvature of the stomach indented and the viscera displaced to the right by a mass corresponding in position to the spleen. The first blood counts showed no excess of erythrocytes but a count on October 4th, 1927 gave haemoglobin 104 per cent, erythrocytes 7,800,000 per cmm, white cells 21,000 per cmm (of which the polymorpho-nuclear neutrophils were 74 per cent and the lymphocytes were 13 per cent). There could be no doubt that the case was one of true splenomegalic polycythaemia (the Vaquez-Osler disease or erythraemia). The patient was thin and her face was pale-browned in hue, later rather high-coloured and telangiectatic in appearance. The fauces were deep red and the whole picture was fairly typical of erythraemia. A most important feature however was the presence of high blood pressure which had apparently been first noted during her visit in Switzerland. The brachial systolic blood pressure was on several occasions as high as 280 mm. of mercury.

It should likewise be mentioned that her liver could not be felt and there was no evidence of any abdominal neoplasm. None of the superficial lymphatic glands were enlarged. The heart was not obviously hypertrophied. The urine showed nothing abnormal excepting a trace of albumin. The blood urea (October 7th 1927) was 0.04 per cent. The blood serum gave a negative Wassermann reaction. The faeces were examined for occult blood with nega-

the result. The patient was edentulous. The menopause had occurred about September, 1926 but since then there had been occasional irregular very slight losses. Like some of her relatives, she had been subject to occasional migraine-like attacks. The various reflexes were normal. There were no retinal haemorrhages or optic neuritis.

Treatment by a restful life and a non-stimulating diet with occasional blood letting led to temporary apparent improvement. In March 1928 however mental confusion developed, together with some loss of power in the right hand and occasional diplopia. From the beginning of April until her death the patient was troubled by recurrent pain and distension in the abdomen sometimes with a few days pyrexia. A small tender mass was felt low in the left iliac fossa and partial obstruction probably due to diverticulitis in the pelvic colon was diagnosed (F. J. B.). The rectum was always empty and ballooned. Improvement in the mental and parietic conditions took place for a time. Early in June 1928 the little toe of the right foot became gangrenous and she died on June 17th after having been more or less unconscious for two days. The last brachial systolic blood pressure taken (May 30th) had been 260 mm. of mercury. The maximum registered in her case was 280 mm. The last blood count had been on May 23rd when the erythrocytes numbered 8,900,000 per cmm (the highest erythrocyte count noted in this case), and the white cells were 26,000 per cmm. The haemoglobin was 110 per cent.

For an account of the necropsy and the microscopic examination we are indebted to Dr. W. J. Carnegie Dickson, who made a most careful post-mortem examination, about thirty-six hours after death. We have confined ourselves to what appear to be the essential points.

There was gangrenous discoloration of the right small toe. The subcutaneous and extra-peritoneal fat was reduced to a minimum and had a congested appearance, the blood vessels especially the larger veins being very prominent and full of rather thick viscid and somewhat dark blood.

The heart weighed 250 grams (9 ounces) and though the whole organ was rather small the left ventricle was relatively hypertrophied. There was considerable coronary sclerosis, very little atherosclerosis of the arch and descending thoracic aorta.

The lungs were somewhat emphysematous and showed hypostatic congestion.

The liver was comparatively small, weighing

990 grams (35 ounces) and was not cirrhotic. Microscopically there was no leukaemic infiltration. The reticulo-endothelial cells appeared rather diminished than increased in numbers and very inconspicuous.

The gall bladder contained a little viscid orange-coloured bile and 32 smooth rounded or slightly faceted cholesterol gall stones varying in size from small peas to thick beans.

The spleen was considerably enlarged, weighing 480 grams (17 ounces) and measuring 6½ by 3½ by 1½ inches. It was free from areas of infarction and microscopically (see Fig. 2) showed general fibrosis of the reticulum, the Malpighian bodies (lymphatic nodes) having practically completely disappeared. It was congested with blood and there were small areas of diffuse haemorrhage. The endothelial cells of the sinuses, and also of the reticulum, were comparatively small in size and there was very little evidence of phagocytosis and destruction of erythrocytes.

The left kidney was small and macroscopically and microscopically fibrosed. It weighed about 40 grams (under 2 ounces). There were three small calculi in the pelvis, the wall of which were

FIG. 1.—Microscopic appearance of the bone marrow from the centre of the shaft of the right femur. (×400.)

* Cf. F. Parkes Weber, *British Medical Journal* 1925 1 p. 1108 and 1927 11 p. 98; *Lancet* 1925 11 p. 1108.

thickened. The right kidney weighed 127 grams ($4\frac{1}{2}$ ounces) and microscopically the larger arteries (interlobular etc.) showed considerable thickening of both middle and inner coats whilst the glomeruli showed hyaline swelling of their capillaries. There were decided degenerative and necrotic changes in the epithelium of the convoluted tubules which were however, doubtless terminal in nature, or rather of *pseudo-ante mortem* and partly *post mortem* origin.

There were old fibrous adhesions of the great omentum and chronic adhesions of the left broad ligament and fallopian tube to the omentum and left wall of the pelvis. The sigmoid flexure and the rectum were much elongated and convoluted. There was excessive sacculation in the pelvic colon. The caecum was filled with pulsatious faeces and the transverse colon sigmoid flexure and upper part of the rectum contained marbled like scybulous faecal masses, and the mucous membrane showed catarrhal changes.

The uterus was small and atrophied and on its anterior surface an old partially calcified small fibromyoma projected. The ovaries showed marked fibrotic atrophy.

Bone Marrow.—The bone marrow of the shaft of one femur which was examined was red as also was that of the cancellous bone and of the ribs. Microscopic examination of the bone marrow showed great excess and activity of erythroblastic tissue and also to a lesser extent excess of leucoblastic tissue. There were small areas of diffuse haemorrhage. A striking feature of all the bone marrow preparations was the unusually large number of giant cells of the megakaryocyte class (see Fig 1). An equally striking feature was the relative absence of evidence of phagocytosis and processes of blood destruction by the endothelial cells.

There was nothing of importance to note in regard to the pancreas, thymus, thyroid, pituitary gland and pineal body. The calvarium was of medium thickness but very compact and relatively heavy. There were arterio-sclerotic changes in the cerebral arteries and terminal local thrombosis in some of the vessels with consequent softening of the right supramarginal and angular gyri. There were as above mentioned arterio-sclerotic changes in many of the medium sized visceral arteries especially coronary, renal and cerebral and the ganglion of the left small toe was probably of arterio-sclerotic origin.

REMARKS

The high blood pressure during life in this case of erythraemia was explained by the renal and vascular changes demonstrated at the *post mortem* examination. It is clear that the blood destruction in the spleen and bone marrow, as evidenced by the phagocytosis of erythrocytes etc., was not relatively excessive. But even if blood destruction in most cases of erythraemia were relatively deficient the abundant and invariable evidence of greatly excessive erythrocyte formation shows that deficient erythrocyte destruction (as has been long recognized) is not the main cause of the polycythaemia rubra. Nevertheless, as Dr Carnegie Dickson points out to us, the relatively deficient blood destruction in the present case might well be contrasted with the evidence of excessive destruction of erythrocytes in the bone marrow and spleen (reticulo-

endothelial system) of, let us say, typical cases of pernicious (Addisonian) anaemia. In regard to the great excess of megakaryocytes in the bone marrow, it is rather unfortunate that no exact count of the thrombocytes (blood platelets) in the circulating blood of the present case was made. In ordinarily stained blood films the thrombocytes did not appear to be in excess.

We are indebted for the illustrations to the kindness of Dr Carnegie Dickson. Fig 1 is to illustrate the microscopic appearance of the bone marrow from the centro of the shaft of the right femur, where in ordinary persons there is only fatty marrow. It shows excessive erythroblastic activity, the cells being mostly erythroblasts. To a lesser extent there is evidence of leucoblastic activity, but this was more obvious in the rib marrow. An especial feature is the large number of megakaryocytes, which were scattered throughout the sections of the marrow in both femur and rib. Fig 2 is from the spleen, it shows fibrosis of the reticulum, with more or less disappearance of the lymphocytes of the Malpighian corpuscles and pulp.

The engorgement with blood was better shown in other sections. In both the bone marrow and the spleen there is no evidence of any excessive destruction of erythrocytes.

PARAPHIMOSIS OF THE CLITORIS

BY

R J WILLAN, MVO, MS, FRCS,

HONORARY SURGEON AND LECTURER IN CLINICAL SURGERY TO THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE

On September 18th, 1928, I was asked by Dr Hepplewhite of Wallsend-on-Tyne to see in consultation with him a female child, aged 9 years and 4 months, who had a painful swelling at the vulva. Five days previously when out for a walk with an aunt it was noticed that the child was limping, but she denied that anything was the matter. On the day before I saw her she complained for the first time of pain, and only then was she examined, and a painful swelling in the region of the clitoris was noticed, but nothing was done until the next day, when Dr Hepplewhite was called in.

I was informed that the child was a devotee of a "fairy cycle," and the parents thought that the child had probably injured herself by the saddle when riding this. Dr Hepplewhite made a diagnosis of paraphimosis of the clitoris a diagnosis which proved to be correct.

FIG 2.—From the spleen, showing fibrosis of the reticulum with more or less disappearance of the lymphocytes of the Malpighian corpuscles and pulp ($\times 400$)

On examination there was nothing unusual to note about the child's development, there were no signs of puberty. The normal site of the clitoris was replaced by an oedematous swelling the size of a large walnut. The swelling was the exact size and shape of the glans penis in an adult male in a case of hypospadias, it was rounded and smooth, with a vertical groove on its ventral surface. Immediately behind the swelling was a constriction with a circular area of ulceration similar to that seen in

FIG. 1.

a neglected paraphimosis in the male the area was so exquisitely tender that a complete examination was not tolerable.

The diagnosis of paraphimosis of the clitoris was confirmed by an examination under a general anaesthetic. An attempt to divide the constricting band and reduce the paraphimosis was unsuccessful, and as there was a tendency to haemorrhage the clitoris was ligatured off. A full examination of the genitals failed to disclose any abnormality.

A photograph of the child was taken, and Mr S. A. Sewell has made a drawing from it (see Fig. 1). He has also drawn the specimen, which is the actual size when removed (see Fig. 2). It has been preserved by injecting gelatin into it.

FIG. 2.

It is impossible to say how the hood of the clitoris came to be displaced backwards. The mother said that she had never noticed any obvious deformity about the child's external genitals so probably the prepucial size was not of abnormal size. There is no reason to think that it was due to masturbation, therefore, accepting this premise, I regard the 'furry eye' saddle as the probable cause which displaced the prepuce backwards and gave rise to the condition.

The child was seen on November 1st, when she was fit and well. The wound was healed and the scar most satisfactory.

Having no knowledge of a similar case I applied to the librarian of the Royal Society of Medicine, who gave me permission to state that, despite a prolonged search, he is unable to find any reference to the condition in the literature. He showed me that there were numerous references to phimosis of the clitoris due to adhesions of the prepuce

A CASE OF POST-PARTUM ANALMIA

BY

J. AILMAN POWELL, M.D.,

HONORARY PHYSICIAN, CHELTENHAM GENERAL AND EYE HOSPITALS

AND

J. B. DAVY, M.B.,

HONORARY PATHOLOGIST, CHELTENHAM GENERAL AND EYE HOSPITALS

The following case shows how important the correct treatment is in this somewhat rare condition.

A woman aged 35—who had had no former illnesses except appendicitis cured by operation at the age of 21—was delivered of her first child in 1918. Labour lasted for three days and was followed by severe post partum haemorrhage. The baby lived a few hours. The patient ran a temperature for several weeks after the confinement was anaemic and suffered from severe headaches and occasional rigors. *B. coli* were present in the urine. There was right iliac pain for three months afterwards which was diagnosed as ovaritis. Her second confinement took place in 1920 and was uneventful and the puerperium normal.

A few days before her last confinement on November 3rd, 1926 she had a mild attack of influenza. A few *B. coli* were found in the urine during the last weeks of pregnancy, for which urotropine was administered. The delivery was a breech, the baby was born without difficulty and there was no trouble with the placenta which was normal in appearance. There was no post partum haemorrhage.

On the following day the patient complained of severe frontal headache and looked alarmingly anaemic as though she had had a severe haemorrhage during the night. Inquiries showed that there had not been any haemorrhage, and examination revealed nothing abnormal. The headache continued and was accompanied by impairment of memory, general weakness and progressive anaemia. The temperature began to rise in the evening up to 101° F. and the patient appeared to be very ill. There was no evidence of puerperal sepsis. The liver and spleen appeared normal, there was no history of sore mouth. The tongue, teeth and gums were healthy. Subsequent x-ray examination showed no sign of apical sepsis. The heart and lungs were healthy except for a haemic murmur which has since disappeared. Blood culture was negative. Report by one of us on blood examination on November 18th was as follows:

Haemoglobin	33 per cent
Red blood cells	1,603,000 per c mm
Colour index	1.1
Leucocytes	6,500 per c mm
Differential count	
Polymorphonuclears	70.5 per cent
Lymphocytes	20.3
Large mononuclears	4.7
Eosinophils	4.0
Mast cells	0.7
	100.0

Eight megaloblasts, six normoblasts and one microblast were noted in counting 300 leucocytes. Poikilocytosis and anisocytosis were well marked and there were many macrocytes and microcytes. Basophilia and basophilic stippling of red cells were very prevalent. Many of the polymorphonuclears showed immaturity and degenerative changes.

The blood picture is that of pernicious type, such cases arising in the puerperium appear to be particularly amenable to treatment especially by transfusion and a high proportion of recovery has been reported.

At this stage she was seen by Dr J. R. Collins who could find no evidence of puerperal sepsis or other focus of infection.

Another blood culture was negative. She was put on iron and on emic and hypodermic injections of adrenaline and dilute hydrochloric acid 1 drachm three times a day. In spite of treatment she continued to go downhill and on November 26th the report on her blood was:

Haemoglobin	25 per cent
Red blood cells	1,270,000 per c mm
Colour index	1.0
Differential leucocyte count	
Polymorphonuclears	60 per cent
Lymphocytes	30
Large mononuclears	4
Eosinophils	5
Mast cells	1
	100

Owing to the paucity of cells in the extremely thin films which the watery blood afforded only 100 leucocytes were counted. There were three megaloblasts, five normoblasts and one microblast to 100 leucocytes.

The blood picture is that of the most grave degree of pernicious anaemia, poikilocytosis, anisocytosis, basophilia and basophilic stippling are seen in every field. The most favourable reading possible of the haemoglobin content has been given, this is always some personal element to be allowed for in this estimation. The patient has lost 9 per cent of haemoglobin and 330,000 red blood cells per cubic millimetre since the last examination eight days previously. This needs no further comment. The vomit is devoid of free hydrochloric acid.

The patient's condition was then very grave, and after consultation with Dr Collins she was given a transfusion of 470 ccm of citrated blood by Keynes's method, her husband who was of the same group acting as donor. This was followed in a quarter of an hour by a severe reaction, and a temperature of 104°F , which lasted for four hours. No haemoglobinuria followed the injection. Her clinical condition steadily improved after the transfusion, her temperature became normal in two days, her appetite returned, and her headaches disappeared. The regeneration of the blood is shown in the accompanying graph. The loss of cells and stationary curve for haemoglobin between December 16th and December 30th corresponds to a pyrexial attack, during which the iron and arsenic were stopped. A gastric analysis (which was not complete as the patient vomited the tube at the end of an hour) showed achlorhydria.

She is now twenty-three months after the confinement, apparently in perfect health, taking hydrochloric acid regularly.

This case illustrates the importance of blood examination in puerperal anaemia, and the necessity of blood transfusion when the examination reveals an anaemia of pernicious type. There is no doubt in our minds that had it not been given the case would have ended fatally.

DISCUSSION

We consider that the case described above fulfils the conditions necessary for a diagnosis of pernicious anaemia: colour index above unity, accompanying a profound anaemia, the presence of numerous macrocytes and some

megaloblasts in the blood, paucity and abnormally large size of blood platelets, and absence of free hydrochloric acid from the gastric contents. Macrocytocytes (Cooke, 1927) were not found in this case, though we have seen them in other cases of pernicious anaemia.

Indications of a possible septic cause for the anaemia were entirely lacking. The uterus involuted in a normal manner. Moreover, the clinical signs of a serious anaemia were detected on the day following that of delivery. Pyrexia, which is usually observed in acute cases of pernicious anaemia progressing unfavourably, was present and showed an upward tendency until transfusion changed the whole aspect of the case.

It is admitted that there is some difference of opinion both as to the diagnostic importance and criteria of megaloblasts. Naegeli considers that large nucleated red cells, named by him "macrocytes," are seen in various forms of anaemia and have not the significance of the megaloblast of pernicious anaemia, the former being distinguished by a basophil cytoplasm. The megaloblasts observed in the case we describe all showed, to a greater or less degree, basophilic cytoplasm. But if, with most authorities, we regard the character of the nucleus as the criterion and basophilia of the cytoplasm to be an indication of immaturity, then the large nucleated red cells of our case were true megaloblasts.

There appears to be a difference, not yet clearly defined, between the pathogenesis of pernicious anaemia occurring in connexion with pregnancy and the puerperium and that of the disease arising apart from these states. Larrabee (1925) has directed attention to the striking effect of a transfusion, an effect well illustrated by our own case. Larrabee reported seventeen cases of severe anaemia arising in the course of, or shortly after, pregnancy, not attributable to other complications. In eight of these the blood picture was that of the pernicious type; four were transfused and recovered; three of the remainder, who were not transfused, died. He considers that one transfusion suffices to check the progress of the disease, an opinion substantiated

by our experience. Other writers have, on occasion, found repeated transfusions necessary.

Piney (1927) classifies the pernicious anaemia of pregnancy under the heading of "metabolic cases," and suggests that a congenitally defective haematopoietic system is unable to withstand the strain of pregnancy. Were this hypothesis sound, the first pregnancy would be expected to induce the disease. Our patient had successfully passed through two previous pregnancies, one of which, moreover, was followed by severe (post-partum) haemorrhage—an additional strain which would surely have overwhelmed a congenitally defective haematopoietic system.

Evas (1926) states that Faust and Talquist claim to have isolated the haemolytic substance from the body of the worm in *dibothriocephalus* anaemia, and to have identified it as cholesterol oleate, but he says that no foreign haemolysin has ever been demonstrated in the blood of cases of pernicious anaemia, and that increase of the normally present haemolytic agents (unsaturated fatty acids) is not proven. We are not aware whether the pernicious anaemia of pregnancy came within the scope of these investigations.

Rowland (1924) states that Hofbauer showed that a syncytial haemolysin in the ectodermal cells of the chorion is the source of the haemolysis of early pregnancy and of

the iron synthesis in foetal blood formation. The urine of pregnant women contains more iron than usual. According to Hofbauer an antihemolysin is formed, during the second half of pregnancy, in the maternal blood, and consequently the physiological anaemia of early pregnancy is overcome, a normal blood count being established by the ninth month. If antihemolysin formation fails, active haemolysis continues and progressive anaemia results. Rowland reports two cases, his paper contains a valuable discussion of

the disease. One of his cases died on the twelfth day after parturition, owing, in his opinion, to delay in resorting to transfusion until the disease was too far advanced.

The distinctive features of pernicious anaemia in pregnancy make Hofbauer's theory an attractive one. Cholesterol acts as an antihemolytic agent against many haemolytic substances, an increase in blood cholesterol occurs in pregnancy, and a diminution in pernicious anaemia. We regret not having made a blood cholesterol estimation in our case.

Pernicious anaemia in pregnancy is usually considered to be extremely rare in England. Lovell Gulland (1927), however, says "it is not very uncommon and, in my experience, is not usually fatal, though it may be so." He does not state whether his cases were transfused.

Green-Armytage (1927) states that anaemia of the pernicious type is not uncommon in pregnant women in India, and has a high mortality. Facilities for transfusion were not, it appears, available at his hospital. There are so many causes of anaemia in the tropics that his cases may be of a different nature to those reported from Europe and America.

Hoskin and Cairns Cadlo (1927) have recently reported a case in the *Lancet*. Their patient had suffered in India from a disease resembling sprue—a possible etiological factor which makes one hesitate to accept their case as a true pregnancy pernicious anaemia. Our patient had not been out of England, and at no time had suffered from symptoms suggestive of sprue. Hoskin and Cairns Cadlo transfused their patient but a gain of 6 points in

haemoglobin and of 380,000 red blood cells per cubic millimetre had taken place in the seven days following admission to hospital, and before transfusion was resorted to. The colour index in their case was below unity until the red blood cell count and haemoglobin value had become approximately normal—some ten weeks after admission to hospital.

The question arises whether a genuine cure—security from relapse—has been attained in our case. We venture to think that it has, and have delayed reporting the case for more than twelve months to afford stronger grounds for our belief. The blood now shows no indication of pernicious anaemia, and the patient is in excellent health. Twenty-three months after her confinement she still takes hydrochloric acid regularly.

WELSH PHYSICIANS AND THE RENAISSANCE

BY

F. ROLAND WILLIAMS, M.A., M.R.C.S., I.R.C.P.,

MAELCLOCHIOG

IN Wales in the sixteenth century there existed two distinct medical traditions. The one tradition clung to the soil and the peasantry, the other was a scholarly tradition, nurtured in the older universities of Western Europe and imbued with the spirit of the new learning.

The popular tradition was of course, the older. It had its origins in folk beliefs and superstitions many of which must have been as ancient as the *menai lion* and the *crannichan* which are dotted over the bare hillsides of Cornwall and North Pembrokeshire. Mingled with these folk beliefs were survivals of the more bizarre and more purely superstitious elements in mediaeval Welsh leechcraft.

The vogue which this tradition must have enjoyed in the sixteenth century may be inferred from the fact that many usages typical of it still survive among the Welsh peasantry in remote, old-fashioned districts. Let me give some instances of such survivals.

Even a casual perusal of the old Welsh Leech Books of the Middle Ages leaves no doubt as to their preoccupation with sheer filth and ordure as therapeutic agents. That kind of belief you may meet with to-day in out-of-the-way districts of Carmarthenshire or Pembrokeshire, where human urine is still used occasionally as a lotion for itching eczemas, and cowdung poultices are not unheard of. Quite a short while ago, too, in Pembrokeshire, a colleague, called in to attend to a shotgun wound of the buttock, discovered that pig manure had been lavishly applied as a styptic and first-aid dressing pending his arrival.

Another stock feature of folk medicine and mediaeval leechcraft was the fantastic employment of drugs of animal origin.

Eve of newt and toe of frog
 Wool of bat and tongue of dog
 Adder's fork and blind worm's sting
 Lizard's leg and howlet's wing

—all had their place in that strange endocrinology which derived its origin from the "doctrine of signatures." A few such simples still linger in use as domestic remedies in the Principality. Bear's grease, so much lauded as a remedy in the Middle Ages, and a relic perhaps of the therapeutic theories of the hunter stage, may no longer be

fashionable, but few rural practitioners in Wales will have failed to observe the esteem in which goose grease is still held as an ointment for wheezing chests and sore throats. Spider's web has still some vogue as a styptic for cuts, and salt bacon is quite a favourite dressing for boils and abscesses. Even more primitive medicinal practices may be met with in Wales to-day. Students of the mediaeval Welsh *Doct of the Wyddfael Physicians* will have frequently encountered in its pages a ritual in which some small animal, such as a toad, is directed to be incinerated, pulverized, and administered to a patient in food or drink. I am credibly informed that such a procedure was carried out in Cardiganshire a little over a year ago, when, on the advice of a "wise woman," a mouse was roasted alive and the pulverized ashes were administered in porridge to a small boy who suffered from emesis. Charms and spells are hardly to be met with nowadays, but during the last century they were still sometimes hung in stables to ward off diseases from animals.

Since its survivals are so numerous in this our own time it may safely be inferred that this older tradition had a very great hold upon the mind of the ordinary man in sixteenth century Wales, and it is by contrast with those deep-rooted beliefs and practices of an older day that we may best realize how profoundly the new learning of the Renaissance influenced the practice of medicine in Wales.

It is true that the new tradition which grew up in Tudor times was empirical; its limitations and its errors are very obvious when looked down upon from those lofty peaks of scientific attainment which have been climbed since. But, viewed historically, it reflected quite worthily the mentality of a nation which had newly passed through the flame of a great intellectual revolution. Those who upheld it made no account of charms, magic, or the merely bizarre, they strove, within the limitations of the age which engendered them, to be scientific, temperate, and sane in their deductions and practice. But that which above all characterized these newer practitioners, and which stamped them especially and vividly as products of the Renaissance, was the breadth of their cultural outlook and the way in which they laboured to extend the boundaries of learning in other subjects besides medicine, while pursuing their everyday vocation as practising physicians.

There was a converse to that also. For, just as the physicians made excursions into other domains of learning, so did divines and the better educated country squires also invade the realms of medicine. Quite considerable collections of medical books were to be found in the libraries of some of the country houses, such was the case at Gwydir, the seat of the Wynn family. There is preserved among the Wynn papers a catalogue of twenty-one medical treatises which formed part of the Gwydir library in 1647. Most of these works belonged to the previous century, and had probably been acquired in Tudor times.

William Salesbury of Llanrwst, a distinguished theologian and philologist (acquainted, it is said, with nine languages besides Welsh and English), also had medical interests. To him is attributed the authorship of one of the medical "herbals" of the period.

The most interesting figure amongst the divines who practised medicine was Sir Thomas ap Williams, curate of Trefriw about 1573, who had a very considerable repute in North Wales as a physician. Several of his letters of advice to Sir John Wynn of Gwydir are preserved among the Wynn papers. His prescriptions, written some in Welsh and some in English, were richly sonorous of the pulpit, and liberally punctuated with *amens* and benedictions. "God be praised," he once wrote to Sir John, "that your worship hath had stools, otherwise it had been necessary to chastise *Protegat te nomen Dei Jacobi*."

Sir Thomas ap Williams's medical activities were a bugbear to at least one of Sir John Wynn's more orthodox advisers, Alexander Read who wrote indignantly to the baronet in 1610 protesting against the curate's presumption in posing as a physician, and pouring scorn on "his ineffectual old simples."

Read was a Scotsman by birth, and became one of the most popular and skilful general practitioners of his day. Before he became lecturer in anatomy to the Barber Surgeons in 1632 he lived at Holt on the Welsh border

* Read in the History of Medicine Section of the Annual Meeting of the British Medical Association Cardiff, 1923.

and his services were greatly in demand, not only throughout North Wales (where he attended the Wynns and other prominent country families), but also as far afield as Monmouthshire.

Called once to Newport to see a tailor with an injured leg, Read promptly amputated the limb above the knee with a carpenter's whip-saw, arresting the hemorrhage with a sort of mortar compounded of white of egg, unslaked lime, and hare's fur. He published several books on medicine and surgery, but his activities belong mainly to the seventeenth century, and so fall rather beyond the scope of this paper. For the same reason another of the physicians of the Wynn family, John Bullcley of Cleiflog in Anglesey, must be dismissed with just the passing mention of his name, for I wish to direct your attention more especially to those Welsh physicians of the sixteenth century who have claims to be remembered not only as physicians, but as pioneers of the new learning in other fields of knowledge also.

Robert Recorde of Tenby

Of these men, the earliest, and in some ways the greatest, was Robert Recorde of Tenby. He was a physician of repute, and also one of the great mathematicians of the sixteenth century. In this light it is interesting to compare him with those other notable Renaissance mathematicians, Arnold de Villa Nova, Neander, and Hieronymo Cardano, who, like Recorde, were also physicians, Cardano being first of all professor of mathematics at Milan and then professor of medicine at Pavia and Bologna.

Born in Pembrokeshire in 1510, Robert Recorde studied first of all at Oxford, becoming a Fellow of All Souls in 1531. Later he studied and taught mathematics and medicine at Cambridge, taking his M.D. there in 1545. He then returned to Oxford, where he taught arithmetic and mathematics. These sciences, according to Wood, "he rendered so clear and obvious to all capacities that none ever did the like before him in the memory of man." Rhetoric, anatomy, music, astronomy, cosmography also came within the ambit of his vast learning. He was an authority on coinage, and was at one time comptroller of the Mint. He was, moreover, one of the first in Britain to adopt the Copernican system of astronomy. The work he did in furtherance of the study of geometry, algebra, and arithmetic was important and lasting. To him we owe the invention of the sign of equality ($=$), and it was he who popularized the use of the signs *plus* (+) and *minus* (-).

As a physician he was not an inconsiderable figure. In 1547 he practised in London, indeed, he is said to have been physician to Edward VI. and Mary. He wrote a treatise on anatomy which is unfortunately not now extant, probably it was what he planned it to be—"an exact book with goodly pictures aptly framed."

One of his medical treatises does, however, still exist—*The Urinal of Physick*—a beautifully printed little volume, published in 1548 and dedicated to the Wardens and Company of the Surgeons in London. It was meant particularly for the enlightenment of surgeons so that they might not so often confound medical with surgical conditions "and surgery be slandered thereby." It was also intended for popular perusal so that the laity might be enabled to describe their urinary symptoms more exactly and helpfully when consulting a physician. In this connexion, Recorde "exhorts all men not to mock and jest with any physician (as some light wits do), tempting them with beast's stale instead of men's urine or bringing them men's water for women's."

The little book lays down the classical canon of uroscopy as derived from "Hippocrates, Galen, Aegnetas, Pliny, Constantinus Africanus, Dioscorides, etc." Recorde was careful, however, to stress the fact that the history of the case and the general observation of the patient were equally as important as the study of the urine in arriving at a diagnosis. He was thus no mere empirical uroscopist.

In spite of, or because of, the multitude of his intellectual activities, Recorde would not seem to have prospered, for he got into financial straits and died in the King's Bench prison in 1558.

Humphrey Llwyd of Denbigh

In Humphrey Llwyd of Denbigh the sixteenth century produced another Welsh physician who was notable for the breadth of his culture and for his pioneer work in new fields of knowledge. He was one of the cartographers of the period.

Born in 1527, Humphrey Llwyd proceeded to Oxford, to Brasenose College. He graduated as Master of Art, and then proceeded to study medicine. Afterward, for fifteen years, he was private physician to Lord Arundel, the Chancellor of the University. He then returned to Wales, living and practising at Denbigh Castle, where he died in 1568.

Humphrey Llwyd was devoted to music, and was an industrious and erudite writer on Welsh history and antiquities, but it was his work as a geographer which formed his chief contribution to the advancement of the new learning. Through his fellow townsman, Sir Richard Clough of Antwerp and London, he came into close contact with Ortelius, who, in his *Theatrum Orbis Terrarum*, referred to Llwyd as "the noble and most learned man," who supplied him with maps of England and Wales for his *Ancient Geography*. Many prints of Humphrey Llwyd's maps are still extant.

He wrote two medical works of note. The first, *The Judgement of Urine*, published in 1553, was a translation of Vassaeus's work on uroscopy. The second, published posthumously in 1585, and entitled *The Treasury of Health*, was a translation of the *Thesaurus Pauperum* of Peter Hispanus, together with aphorisms of Hippocrates, and the views of Jacobus de Partibus on therapeutics. To this rather conglomerate work Llwyd added, as original contributions of his own, a commentary on "the causes and signs of every disease," and a kind of Index Therapeuticus and Guido to Dispeasing—"a compendious table containing the purging and comfortative medicines with the exposition of certain measures and weights."

The book is interesting in that it reveals the kind of therapeutics used which guided the practice of a well-qualified physician of that period. None of the remedies advised by Humphrey Llwyd on the authority of his original authors can be described as grotesque or revolting. Even mummy did not occur in his materia medica, though mention was made of ivory, lapis lazuli, and confection of pearl. For the most part there was sound empirical common sense behind his prescriptions. Juniper "to comfort the reins", camphor and lavender "to comfort the heart", mints and oil of bitter almonds "to comfort the stomach", pillule of iubarba for the liver, oil of cardamoms and oil of pepper for colic, and oil of caraway "for the paynes in the smal guttes." A syrup "of the pillages of oranges" was recommended as a stomachic, confection of ginger "for all ventosities and inflations of the stomach," and syrup of poppy for a hacking cough that interfered with the patient's sleep. His favourite drug would appear to have been oxymel squill, which was advised for a variety of conditions. Mercury would not seem to have found any favour with him, but arsenic, in the form of lozenges, was recommended "to heale wyld fyre and ringwormes." One has only to compare the therapeutics of this book of Llwyd's with *The Welsh Leech Book* and other similar books inspired by mediæval standards to be able to gauge the enormous influence of the new knowledge and the new spirit of the Age of Discoveries upon the actual everyday practice of medicine in Wales.

The Welsh Grammarians

I now turn to that important and interesting aspect of the Renaissance which expressed itself in the work of the translators of the classics and the patient labours of the grammarians who helped to reveal the intrinsic beauty and literary potentialities of the "vulgar tongues" of western Europe.

At least one of the early translators of the classics into English was a physician practising in Wales. Thomas Phaer translated nine books of Virgil's *Æneid* into English verse while living at Cilgerran in Pembrokeshire. This was for some years the most popular English translation of the

Arctur Phyl also wrote two medical treatises: *A Goodly Brief Treatise of the Pestilence* and *The Hygiene of Health*, a popular manual of hygiene of the type of *Doyle's Castle of Health*.

The Welsh grammarians were many, and although some of them seem to have been Catholics, their work culminated in Wales as in England, in translations of the Scriptures, which became not only theological canons but canons also of literary style and diction. Several of these Welsh grammarians were physicians who sought relaxation from the cares of practice in the study of what one of them characteristically enough termed "the anatomy of language."

St Thomas ap Williams, curate and country physician, who was one of the many medical advisers of Sir John Wynn of Cwmdwr, compiled a Welsh Latin dictionary. Henry Salesbury of Denbigh, in Denbighshire, published a Latin grammar of the Welsh language in 1593. Salesbury was a graduate of Oxford and a physician of some eminence in North Wales. He also compiled a Latin Welsh dictionary, but it was never published.

The most picturesque, the most typical and the most learned of the Welsh grammarians of the Renaissance was, however, another physician—Doctor Rhys. John Dafydd Rhys was born at Llanfuchlan in Anglesey. He studied at Oxford, but did not graduate at that university. In 1555 he went abroad—perhaps as a recusant, for Wood stated that he lived and died a Catholic. However that may have been his wanderings brought him at last to Italy, the homeland of the Renaissance, where he studied medicine at the ancient university of Siena in Tuscany. He graduated as doctor of physic and then became moderator of the school at Pistoia. While in Italy he acquired a profound knowledge of Italian, and wrote two grammatical treatises in that language which were published at Padua. One was an introduction to the study of Latin, the other was a guide to the pronunciation of Italian, which became a favourite textbook for Englishmen visiting Italy.

After many years, however, the exile felt again the call of his native hills. He left Italy, that land of light and warmth, and returned to Wales, where he practised as a physician amid the sombre environment of the Brecknock Beacons. He died in Brecknockshire in 1609.

During this last period of his life he wrote a scholarly Latin treatise on Welsh grammar and prosody, and it is by this work of massive learning that he is best remembered by his compatriots. He also published a Welsh translation of Aristotle's *Metaphysics*, but the manuscript of that work has been lost.

His eminence in two lands as a grammarian has overshadowed John Dafydd Rhys as a physician, but he described himself in the preface to his Welsh grammar as "a man of harassed years in the care of the sick and the worries of business."

In the introduction to the same work, too, Humphrey Prichard referred to him as having gained the title of doctor "for his eminent studies in medicine."

The annals of the Renaissance in Wales would be the poorer if time had not preserved for us at least in silhouette the likeness of this insatiable old scholar. He was just such a personality as Browning has portrayed so vividly in *The Grammarian's Funeral*. Hakluyt described his contemporaries as "men full of activity, stirrers abroad and searchers of the most remote parts of the earth." John Dafydd Rhys was just such a one but adventuring for learning as others of his time and generation adventured for spices and gold mouldores.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

RETROPHARYNGEAL ABSCESS SECONDARY TO FOREIGN BODY IN HYPOPHARYNX

A RETROPHARYNGEAL abscess the result of injury due to the swallowing of a foreign body is rather unusual, the condition was found in the following case.

A man aged 45 was admitted to the rural department of the Manchester Royal Infirmary with the history of having swallowed two days previously a piece of chicken bone. He was unable to swallow any solid food, and liquids only with pain and difficulty. There was some obstruction to free breathing.

The senior house surgeon examined him with the mirror and also with Jackson's laryngoscope but was unable to find any foreign body although an X-ray report indicated a small elongated one at the level of the sixth cervical vertebra. Six hours later he was examined under general anaesthesia by Mr F. W. Wrigley, no foreign body being seen.

The dysphagia and pain now increased with rise of temperature to 100.4° F. and two days later he was referred to me by my colleague. On examination with the mirror I found very marked bulging forward of the left posterior pharyngeal wall partially hiding the left arytenoid from view. The left arytenoid and left aryepiglottic fold were very swollen and oedematous, much frothy saliva and mucus was collected about the swelling and larynx. The act of swallowing was very painful and on pressing the larynx over from the right to the left towards the tender site as indicated by the patient a sharp pain was caused. This sign Dr. Cabrilhac regards as

Arrow=chicken bone. Area between continuous and dotted line=swelling of posterior pharyngeal wall. Very black line below in mouth.

definitely indicating the presence of a foreign body. A radiogram taken that day showed a small spicule of bone embedded in the retropharyngeal wall at the level of the sixth cervical vertebra and marked bulging of the wall. The passage of barium paste had been seen obstructed at this point. As the patient was not ready for an endoscopic examination this was postponed until the following morning. During the night he brought up an ounce or more of pus and much mucus with a tracer of blood. In the morning after injection of morphine and atropine under cocaine anaesthesia I passed the short Jackson's oesophageal speculum. The larynx was still very inflamed and oedematous but the pharyngeal swelling was much less. No foreign body was seen but a tear on the posterior wall was found from which pus was expressed as the instrument moved near it. It was thought desirable not to open the abscess further, and the patient was given an adrenaline spray (1 in 10,000) and bismuth carbonate powder. His temperature remained at 100.2° F. for two more days then the laryngeal oedema and post-pharyngeal swelling rapidly subsided and in three days he was discharged swallowing normally.

A subsequent radiogram showed no sign of a foreign body and it seems certain that this was either vomited or swallowed when the abscess broke during the night, after this pressing the thyroid or cricoid cartilage over to the left no longer elicited any pain or increase in the tenderness at the site complained of by the patient. This sign must be regarded as a very valuable one in cases of suspected foreign bodies which are non-opaque to X-rays.

D. LINDSEY SEWELL

Honorary Aurist and Laryngologist to the
Manchester Royal Infirmary

LOCAL ASPHYXIA IN A YOUNG CHILD

SUCH a case as the following seems to be sufficiently rare to merit recording.

A girl aged 2 was whirled several miles in a push-chair on a chilly evening. When she was taken out on reaching home it was found that she was unable to stand and that her feet were blue, swollen and painful. On the next morning (Thursday) the left foot was still affected but the right foot had recovered. In the evening both feet were normal and the child was able to trot.

Dr BROMLEY read a paper on some questions and experiences in routine x-ray work. Dr Bromley explained that the interpretation of x-ray photography was really an interpretation of relative densities, and that it was only by realizing this that x-ray photographs could be confined to the best advantage. He emphasized the great importance of routine in technique, and stated his belief that alterations in technical routine should be made only after the most careful consideration and in the light of accumulated experience. The speaker showed on the screen a large number of x-ray photographs. In those showing bones and joints he indicated the necessity of eliminating the possibility of unusual bone formations before arriving at a diagnosis of fracture. In this connexion he showed instances of the two small ossicles occasionally present, one near the base of the fifth metatarsal bone, and the other in the neighbourhood of the joint between the tarsal scaphoid

and the head of the astragalus. Dr Bromley also demonstrated the shadows thrown by calcareous arteries, and expressed his belief that a radiographer, finding them, should report their presence so that the surgeon might be in a position to vary his treatment in the light of knowledge of the condition of the vessel walls in the neighbourhood of the fractured bone. Dr Bromley explained his technique in the radiography of the alimentary canal; he considered that the addition of flavouring agents to opaque meals was rather a disadvantage than otherwise, since, in his experience they rather tended to make the meal less palatable to the patient than it would otherwise be. Dr Bromley explained thoroughly the diagnostic significance of the crater, the filling defect and the spasmodic incision in the diagnosis of ulcers. He also described the significance of the duodenal cap, its causation and the diagnostic value of its various deformities.

Reports of Societies.

SACRO ILIAC PAIN

At the meeting of the Medical Society of London on December 10th with Dr WALTER CAMP in the chair, a discussion was held on sacro iliac pain.

Dr WILFRED HARRIS, in opening, enumerated the various causes of sacro-iliac sprains and subluxations which followed accidents, mismanaged labours, or congenital defects and occurred much more frequently in the female than in the male. One never expected to find a total dislocation of the sacrum, the most common displacement was a posterior rotation of the sacrum, producing flatness of the back, with more or less obliteration of the normal lumbar curve, such as was seen in an anaesthetized person on the operation table. The diagnosis of these subluxations by x rays seemed almost impossible save in rare instances, a stereoscopic x ray picture of the pelvis might, however, bring out subluxations not to be seen in the ordinary flat negative. Clinical experience of these low-back pains, with their speedy relief following certain measures should convince everyone as to their importance. Chronic pains in the back were frequently diagnosed as lumbago, muscular rheumatism, and chronic sciatica. Dr Harris then described the differential diagnosis. In these sacro-iliac sprains tenderness on pressure over the affected joint was almost constant and the pain would be aggravated by walking, standing, or lying flat on the back. The treatment of sacro-iliac pain, whether by manipulations, under an anaesthetic or not by strapping or the use of other supports, or by arthrodesis was outside the scope of his opening remarks, but the differential diagnosis of a sacro-iliac lesion from sciatica, spinal cord disease, arthritis of the hip, lumbago, and sacro-fibrositis was of great importance from the point of view of treatment. American surgeons particularly had investigated and written about this subject, and had helped to rescue many sufferers with chronic pain in the back from chiropractors and osteopaths. It was always necessary to guard against overlooking injury and muscular strain simulating sciatica. In the routine examinations tests should be made for tenderness over the joint by pressure on and below the posterior iliac spine. Tuberculosis might attack the sacro-iliac joint—tuberculosis of the sacrum or lumbar vertebrae might be recognized by a radiograph—and osteo-arthritis of the hip-joint was another condition liable to be mistaken for sacro-iliac sprain.

Mr P. JENNER VERRALL agreed that at all events until recently x rays were of little value and even the stereoscopic view did not dispel all doubt. For the most part reliance must be placed on clinical findings for the diagnosis. In many persons—in the female more than the male—this joint was congenitally lax. Too early weight-bearing after labour was a fertile source of trouble. Another form of sacro-iliac subluxation might occur after such an accident as the fall of some heavy object on to the lower part of the back while the person was in a stooping position. The symptoms of which patients complained were commonly pain in the back or sciatica, either of

which might be due to a multitude of causes. A history of injury or mismanaged labour might be elicited. In severe cases the gait of the patient was almost pathognomonic. Early and advanced cases differed fundamentally in posture, the early case showed considerable lordosis, the advanced case had a flat and almost vertical lumbar spine and sacrum. Deep tenderness over the joint (which must be distinguished from superficial tenderness due to referred pain) and pain elicited by lateral compression of the pelvic crests were useful signs. He was convinced that uterine displacement was less often a complication, and muscular strain more often a complication, than was thought likely twenty years ago. Sacro-iliac subluxation being accepted as a clinical entity, the treatment was reposition followed by support. He thought the frequency of sacro-iliac displacement had been greatly exaggerated, but anyone who had felt or heard the click while performing the manipulations for reduction, and the rotation of the bone, followed by a clearing up of the condition, must be convinced of its existence. Reduction should be followed by some form of support. In severe cases it was well to allow the patient to rest in bed for a few days with lumbar support, some cases wanted nothing more, but others required a sacro-iliac belt and pad the proper form of which he carefully described. Little or no benefit was obtained from local therapeutic measures such as ionization. Mr Verrall ended with an explanation of a method of grafting of the joint which he had employed in severe cases.

Dr E. J. BRADFORD exhibited a large collection of radiographs of this area of the spine. They were a selection he had made from 3,000 cases, not all sacro-iliac lesions, but lesions and deformities in that neighbourhood and supported the points already brought forward by Dr Harris and Mr Verrall. Special attention was drawn to the number of these cases in which there was a congenital deformity, and also to the variations seen in the articular processes of the sacrum.

Dr C. B. HEALD spoke as one who had been one of Mr Jenner Verrall's very successful patients. He had been an acute sufferer from the condition described. One point not mentioned by previous speakers seemed to him worthy of note—namely, the existence of sympathetic phenomena. He had experienced in association with the condition an extremely painful nightly colic. With regard to the sensations, in his own case he remembered that he did not mind bending, but he had the greatest objection to getting erect at one particular point. During and after the pain the leg felt large, heavy and "woolly" as though it belonged to somebody else of much bigger stature than oneself.

Dr H. A. ELLIS mentioned the diagnostic importance of the specific gravity of the urine in all cases of arthritis. In a case of osteo-arthritis the urine had a high specific gravity and there was excess of sulphates, in rheumatoid arthritis it was of low specific gravity, with deficiency of phosphates and no increase of sulphates. Mr VERRALL, in reply to a question, said that the manipulations were always conducted under anaesthesia with the patient completely relaxed. He thought it impossible to perform manipulation of the sacro-iliac joint otherwise.

CANCER OF THE CERVIX

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on November 23rd with the president Dr CHARLES FITZGERALD, in the chair. Dr BETHEL SOLOMONS, Master of the Rotunda, exhibited a specimen of carcinoma of the cervix, removed by the Wertheim method.

The patient aged 36 was a 5-para whose last baby was eleven months old. Two months after the birth menstruation returned and she had lost blood almost continuously for nine months when she came to the Rotunda. The growth was very extensive locally but did not appear to involve the parametria, bladder or rectum. The operation and recovery were without incident. Dr Bourke reported that the specimen was a solid carcinoma originating from the squamous epithelium of middle maturity. The tumour had infiltrated the cervix but the prostatic urethra was more external than internal. The measurement of a ball section of the growth after removal was 4.5 cm.

Dr Solomons dwelt on the fact that the radical operation was the choice for a case of this type—namely, a growth freely movable and of great magnitude—a large quantity of radium would be needed for such an extensive growth. He employed x rays as a routine post-operative procedure.

Dr D G MADILL, referring to the fact that the patient's 1st confinement had taken place only nine months before the finding of the tumour, asked if there had been any history of difficulty at the confinement, and said he did not think the tumour could have reached its present magnitude in nine months. He considered it probable that there must have been some evidence of malignancy at the confinement.

Professor A H DAVIDSON thought it time for an authoritative statement on the present position of radium and operation in cases of cancer of the cervix to be issued. He had seen very many inoperable cases which had been treated by radium in which the results had not been satisfactory, and could only remember one inoperable case, which had been treated about four years previously, in which there had been no recurrence.

Dr R M CORNER believed that if carcinoma was found soon after confinement the prognosis was favourable, since this meant that it was found in an early stage. He referred to a patient of his who had had a normal delivery in July, 1925, and who in December, 1926, had been sent to him again with a diagnosis of incomplete abortion. He had found a malignant condition, a Wertheim operation was performed, and the patient had been perfectly well since.

The MASTER OF THE ROTUNDA replied that the patient had been confined in the country eleven months previously, and he was informed there was no difficulty in the labour. He agreed with Dr Corbet that a tumour discovered apparently soon after confinement indicated probably a favourable prognosis. He did not believe that sarcoma was likely to be found in the microscopic sections. It was extremely difficult to estimate the results from radium therapy and operation for carcinoma of the cervix. Both depended on the skill of the operator. Heyman of Stockholm was obtaining excellent results with radium, which he used in all cases. His technique was beautiful. It was difficult for men who had not a large quantity of radium, and who had not the experience necessary to obtain the best technique, to compare their results with those of Heyman and others. The same remark applied to the operation. The Wertheim operation was difficult, and the best results were obtained by the man with the largest experience. Dr Solomons said he advocated operation for operable cases and radium for the other types in which, working with Dr Stevenson, he had had some striking improvements. It was an easy matter to pick out the authoritative papers on operation and radium therapy from the others.

Uterine Fibroids

Dr Solomons also showed a specimen of a large fibroid removed from a woman, aged 35, who had been married for one year and had had no previous pregnancy.

There had been amenorrhoea for five months and slight abdominal pain. On examination a soft tumour which was obviously a five months pregnancy was found in the lower abdomen. Separated from it by a slight groove and filling the whole of the rest of the abdomen, was a large, hard, somewhat regular tumour, this was freely mobile and slightly resonant on percussion. An x-ray film confirmed the diagnosis of pregnancy. The spleen shadow was visible and there seemed to be a slight connexion between the pregnant uterus and the tumour. The differential diagnosis lay between a spleen, a mesenteric tumour and a large fibroid or an ovarian tumour. A blood count showed the red cells to number 3,356,000 per c.mm. the haemoglobin was 60 per cent. and the colour index 0.9. On opening the abdomen it was obvious that the condition of the growth was fibroid. It filled most of the available space in the abdomen. Having been freed it was removed from the left cornu of the pregnant uterus and the cavity was stitched. There were four other fibroids in the uterus one of which was removed. There was very alarming haemorrhage from the bed of this tumour which seemed to be over the placental site. The haemorrhage was controlled by suture. It did not seem advisable to remove any of the other tumours, since they did not interfere with the pregnancy, which was still progressing.

The PRESIDENT agreed with the Master of the Rotunda Hospital that the only treatment was removal of the tumour. He thought the prognosis was good. He was specially interested in the diagnosis, because he had recently

seen at Mercer's Hospital a somewhat similar case. The patient had a fairly large tumour filling the middle of the abdomen, which at first suggested a spleen, but the blood count negatived this. The abdomen was opened, and a malignant growth of the mesentery was found.

Imputation of the Fallopian Tube

Professor A H DAVIDSON showed a specimen of myomatous uterus with amputated Fallopian tube. The patient, a woman aged 50, complained of irregular and severe uterine haemorrhage for the past six months. She had been married for twenty six years and had had no children or miscarriages, her menstrual periods had been regular up to six months previously. A fibrous polypus was found protruding from the cervical canal, and a multinodular fibroid uterus. In view of the patient's age Professor Davidson decided to perform hysterectomy. At the operation a peculiar and interesting condition of the right tube was found. There was a complete amputation of the tube at the inner end of the isthmal portion, and there was a thin fibrous cord running from that point to a cystic enlargement filled with caseous material, adherent to, and embedded in, a portion of the omentum. It seemed as if the tube had become parasitic on the omentum. The left tube, the seat of old standing salpingitis, was disorganized. Hysterectomy and double salpingo-oophorectomy was performed. Dr F S Bourke, who examined the tube, had reported as follows:

'A section of the peduncle attached to the large caseous mass consists of a fibro-muscular structure resembling in arrangement the muscle wall of the Fallopian tube. There is no evidence, however, of any epithelial lining. I am unable to say definitely that this is an amputated tube but it seems the most likely explanation for its occurrence in such a situation. Smears of the caseous matters were examined, but no tubercle bacilli were found.'

The PRESIDENT thought that this was an amputated tube, since the lumen of the tube was filled with caseous material.

Dr NIVIAN FALENER suggested that this was a caseous gland, and said that as a rule the caseous mass was in the upper part of the tube. In this case it had been found in the omentum, which he regarded as being rather against the condition being an amputated tube.

CANCER OF THE LUNG

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Iceland in the Royal College of Physicians on November 30th, with the president, Dr T T O'FARRELL, in the chair, Dr J SPEARES reported a case of cancer of the lung.

A man aged 51, had been seen by him on October 5th complaining of pain in the abdomen which passed up and through his chest. He had been ill since May 8th. The patient had had three falls from horses and had suffered from malaria and black-water fever. He looked ill and was slightly anaemic. There was no difference in expansion on either side of the chest and no dullness. There were a few coarse crepitations with harsh inspiration over the lower lobes but no bronchial breathing. The heart and blood pressure were normal but the patient was extremely breathless out of all proportion considering that the heart and lungs appeared normal. There was tenderness over the splenic area and something definitely hard could be felt. The liver contained no lumps but felt unduly hard. There was no fluid in the abdomen. The sputum did not contain tubercle bacilli and the Wassermann reaction was negative. An x-ray examination showed lung trouble, mainly confined to the lower lobes, diagnoses suggested had been specific disease, malignant disease and some unknown factor. The patient went downhill rapidly and died on November 8th towards the end he coughed up purulent sputum and vomited without relation to food.

Dr Speares said that in his experience of tumours of the lung the principal thing noticed was dyspnoea. He drew attention to the fact that in textbooks the statement appeared that in malignant disease of the lung the malignancy was principally in the upper lobes. In this case most of the malignancy, although only secondary, was in the upper lobes. It was difficult to know whether malignancy predisposed to tuberculosis or vice versa.

Dr J T WIGHAM, who demonstrated the specimens, said that the spleen was not large, but was soft, and where it had been adherent to the tumour below it had torn to pieces. The stomach was apparently perfectly normal, and though adherent to the tumour below was not infiltrated at all, there being no primary stomach tumour. The

kidney was larger than normal, and presented remains of nephritis, but not very strongly marked, and apparently of recent appearance. The lung showed the typical appearance of secondary cancer. There was only one nodule in the liver. There was a mass of glands in the mediastinum, but it had only been possible to remove the lung, and practically the whole of the mediastinal glands had been left behind. He thought that the cancer was a pancreatic one, it was solid, there were no signs of necrosis, and it was not in any way an adenocarcinoma. The alveoli of the lungs were filled up.

The PRESIDENT referred to a specimen, which he had shown some years ago at the Academy, of a squamous-celled epithelioma of the lung in which tuberculosis also had been present. He thought the fact that there were no secondary deposits in the liver was in favour of the cancer not being in the stomach.

Dr CHARL MOUNT said that in the last year and a half he had seen two cases similar to that described by Dr SPEARES, and in both there had been a tendency to involvement of the base of the lung. In one case there was a pleural effusion which, when removed, revealed the underlying condition, which had previously been shown by x-ray examination. This patient had also been extremely breathless. In the other case the sarcoma had involved the mediastinal glands as well as both lungs; there was well-marked tuberculosis, with cavitation at the apices of both lungs, and also carcinoma of the colon. Dr H. B. COULDING asked if primary or secondary cancers of the lung were common a few years ago he had had under his care three patients with secondary cancer at the same time, but had not seen a case since. In one of his cases haemoptysis had been well marked, and in another there had been an extensive pleural effusion.

Dr SPEARES, replying, said that in his case there had been no evidence of a pleural effusion. Primary carcinoma of the lung was not so common as secondary carcinoma. Dr WICKHAM, replying, said that sarcomas were much more common in the lungs than cancer. Carcinoma of the rectum and breast very often ended with secondaries in the lungs. Primary cancers of the lung had recently been found to be not so rare as was formerly believed.

Lymphosarcoma

Mr F. J. HENRY read notes of a case of lymphosarcoma in a man sent to him towards the end of February as a case of chronic indigestion. He suspected a chronic gastric ulcer, and this diagnosis was confirmed by x-ray examination. At the operation a large chronic ulcer was found in the pyloric segment of the stomach, but in addition there was a large collection of glands lying high up in the stomach. A gland was excised from the greater curvature for examination, and a gastro-enterostomy was performed well above the ulcer. The patient recovered, and obtained complete ease from his gastric symptoms, but a guarded prognosis was given. Early in October he returned, looking very wasted, there was a large hard mass in the epigastrium, and enlarged glands in the right groin. A gland was excised, and a similar report was received to that of the previous occasion. The patient died in a few days.

Dr J. T. WICKHAM, who demonstrated the specimens said that the tumour was at the back of the stomach, passing down into the pancreas. It was a retroperitoneal tumour pressing forward into the stomach. When he had examined the first gland he had doubted whether it was malignant, as it was fibrotic, with a number of giant cells, which might possibly have been some variety of Hodgkin's disease, but there was no doubt that the second gland was malignant. There was an infiltrating sarcoma in the body of the stomach.

Bothriocephalus Infestation

Dr T. T. O'FARRELL exhibited a specimen of infestation with *Bothriocephalus latus*, this being the third which he had encountered, the previous ones had been recorded in 1916 and 1918.

The patient, a man aged 36 from whom the specimen was obtained, was born in County Leitrim, where he resided for fourteen years. He subsequently lived in Belfast for ten years, then in Blackburn, England, for three years and in Belfast again for three years. He frequently returned to his original

home on vacation, though he had never been abroad. Seven years ago he passed segments of a tapeworm which was not identified. In September 1923 he passed more segments and was treated with filix mas which he passed the present specimen which appeared to be the entire worm, though the head was not recovered.

The patient never exhibited any noticeable anaemia. A blood examination made in November was as follows: red cells 4,440,000 per cmm; haemoglobin 96 per cent; colour index 1.0; white cells 9,280 per cmm. Stained films showed slight anisocytosis with an occasional microcyte but no poikilocytosis. No nucleated red cells were found. The differential leucocyte count per cent was as follows: small lymphocytes 20; large lymphocytes 14; myelocytes 10; polymorphs 52; eosinophils 2; basophils 2. In common with the other cases from the County Leitrim area there was practically no anaemia and no eosinophilia. The patient had eaten freely of fresh water fish including pike but he had also an unusual predilection for raw meat.

Dr J. T. WICKHAM thought the patient must have eaten raw fish, since he did not think that cooked fish caused the worm to appear. He believed that the host must be some animal and not man, or else the worm would have died out. Dr J. SPEARES asked if the head of the worm had been found. The PRESIDENT replied that the patient had stated he never ate anything but thoroughly cooked fish but it was evident that this was not the case. He thought it possible that this worm was fairly common, and should be treated as an ordinary tapeworm. The head of the worm had not been found, and he personally was not satisfied that the worm had been expelled.

Mammary Adenoma

Dr A. B. CLERY showed an adenoma of the breast removed from a woman, aged 28 years, who had first noticed the lump two years ago. Several large veins were present over the breast, extending to the left sternoclavicular joint. The tumour, which was about three and a half inches in diameter, had a definite capsule and contained several cysts. Microscopical examination revealed adenomatous characteristics with marked epithelial proliferation, the cells being in places many layers thick.

The PRESIDENT thought that the condition was not encephaloid cancer, but the growth was much softer than what was usually found in the breast. In some of these cases soon after one tumour was removed another appeared and in some the tumours were symmetrical. Mr HENRY suggested that the growth might be a soft fibro-adenoma of the breast, a condition which was rarer than hard fibro-adenoma. Cases of pure adenoma of the breast were very rare, Sampson Handley had stated that he had only seen one in the whole course of his experience. Carcinomatous transference in cases of adenoma of the breast was rare.

Dr J. T. WICKHAM thought this was a rare form of adenoma. The whole tumour seemed to be made up of glands, and the glands which were visible were really tumours. These tumours originated from a very small focus, and not from a large one, as might be expected.

Boveri's Cerebro-spinal Fluid Test

Dr R. A. O'MEARA read a paper on Boveri's test for the cerebro-spinal fluid. He said that when first introduced this test consisted in mixing equal quantities of a 0.01 per cent solution of potassium permanganate and of the cerebro-spinal fluid. Dr O'Meara used somewhat stronger solutions of permanganate, about 0.02 per cent. He found the reaction of particular value in tuberculous meningitis with a clear cerebro-spinal fluid, he had never found the reaction negative in tuberculous meningitis, and in most cases bleaching of the permanganate occurred within three minutes. The speaker concluded, therefore, that the test might be of great value to the country doctor or the consultant, enabling him to distinguish at the bedside between tuberculous meningitis, with a clear fluid, and such conditions as meningism. He added that the reduction of the permanganate was to be explained not only by increase in protein, but also by the increase in non-protein nitrogen associated with meningitis. Conditions such as dementio paralytica associated with a high protein content rarely gave the reaction, and then only faintly, whereas in meningitis with no more protein in the fluid the reaction was always very active.

The PRESIDENT asked if Dr O'Meara had tested the cerebro-spinal fluid of cases of encephalitis lethargica by this method, and whether it could be used quantitatively.

Dr A. J. R. DUNGAN agreed that the test would be specially useful to those who could not get access to laboratory facilities. He thought it difficult when examining cerebro-spinal fluid to differentiate tuberculous meningitis and encephalitis lethargica unless the clinical picture was very marked. Dr CYRIL MURPHY asked how long it was before "weak" cases reacted to this test, and said that since in doubtful cases a laboratory diagnosis was usually, of very little assistance, Boveri's test should be very useful. Dr A. HALPENNY referred to the difficulty of finding tubercle bacilli in the cerebro-spinal fluid, which made it hard to differentiate tuberculous meningitis and encephalitis lethargica.

Dr O'MEARA replied that encephalitis lethargica tended to occur in epidemics, and, therefore, he had not had much experience of it. In cases of encephalitis lethargica the test did not give a strong positive reaction. He had only encountered one case in which the question of diagnosis between encephalitis lethargica and tuberculous meningitis arose, and in it he had diagnosed tuberculous meningitis from the result of the test. The clinician had not agreed, but the patient died in a few days, which Dr O'Meara regarded as being in favour of tuberculous meningitis, since patients with encephalitis lethargica did not usually die quickly. In this case he had found no tubercle bacilli, but Boveri's reaction was strongly positive. He believed that a good many cases which were recorded with very high cell counts were really cases of tuberculosis in which tubercle bacilli were not found, and were not cases of encephalitis lethargica at all. The reaction was described as being strong if it occurred in three minutes, and as weak if it occurred in three to six minutes.

CHOREA

At a meeting of the London Jewish Hospital Medical Society on November 28th, with Dr A. GOODMAN LEVY in the chair, Dr LEOPOLD MANDEL opened a discussion on chorea.

Dr Mandel said that chorea was easily overlooked, in spite of its widespread incidence, owing to the fact that its early manifestations were mild, yet its cardiac sequelae were devastating in their seriousness. Rheumatic endocarditis amounted to an economic and public problem of national importance. In England over 40 per cent of all deaths from heart disease were traceable to rheumatism. Some 25,000 people in England and Wales—the majority of them in the first three decades of life—died from heart disease, and though the figures for chorea alone could only with difficulty be separated from acute rheumatic cases it must be remembered that at least 33 per cent of cases of chorea showed cardiac lesions. It was important to recognize that there was a rheumatic type of child with an unbalanced temperamental make-up associated with physiological instability. This particular type should be safeguarded as far as possible during school age, not only from conditions which might cause acute rheumatism, but also from being overstrained in its education. An etiological factor of some importance was the part played by infected tonsils and the nasopharynx generally. There was some difference of opinion as regards the benefit of tonsillectomy as a protection against rheumatic disease, but it was the speaker's opinion that complete enucleation of the tonsils, if performed early enough, was a definite prophylactic step against rheumatic diseases generally, and undoubtedly beneficial in the prevention of endocarditis. As regards the signs and symptoms of the disease it was not generally recognized that chorea was associated with an increased temperature. Dr Mandel's observations over a long period of the rectal temperature showed that there was in all cases a mild pyrexia. If more attention were paid to what might be termed the prodromal period the disease would be more quickly recognized. With regard to the cardiovascular symptoms the early recognition of organic heart disease in cases of chorea was a difficult problem. Not all bruits were organic, and the course which he had found wisest was to regard a diastolic or presystolic bruit as evidence of definite heart disease. If the bruit was apical and systolic only he viewed it with suspicion, doubly so if there was evidence of dilatation. If it was more marked

it the base, and the patient was anaemic, it was probably haemic, but in any case all choreic patients should be examined at regular intervals for a period of six years after their initial attack. The medicinal treatment of chorea comprised nerve tonics and sedatives, and anti-rheumatic medicaments. Dr Mandel did not think that drugs shortened the course of the disease by one day, though they might, perhaps, control it. Of sedatives he had found the combination of chloral hydrate, pyramidal, and ammonium bromide the most satisfactory, especially if, in conjunction with it, a small dose of luminal was given at night. Calcium therapy, with or without parathyroid, vaccines, and serotherapy had not yielded any good results. Of the anti-rheumatic drugs sodium salicylate given with moderately large doses of the bicarbonate might have some effect in preventing cardiac complications. The speaker had recently treated a few cases by intrathecal injections of autoserum, and though he had had startlingly good results in two cases his series of cases was too small as yet to permit deductions. The paramount feature in the treatment of chorea was rest.

Dr NAIRN DOAGRE believed that there was a distinct rheumatic diathesis, and a certain type of child whose nervous system displayed particular affinity for the rheumatic toxin, with the result that rheumatism in these children showed itself as chorea rather than arthritis. Poor hygiene and faulty environment were important etiological factors. He outlined the London County Council scheme of dealing with rheumatic disease in childhood, and pleaded for the closer co-operation of the medical profession generally. Dr D. NABARRO said that there was no direct confirmatory evidence that some strain of streptococcus was implicated. He thought that the condition was an allergic one in which some toxin—probably derived from a streptococcus—was the cause of the disorder. Mr H. KRISCH held that tonsillectomy in these cases must be performed not only early, but completely, if good results were to be obtained. The condition of the nasopharynx and sinuses should always be inspected, because sinusitis was frequently overlooked in children. Dr CHATKIN outlined the methods of the London County Council medical school inspection. School medical officers at all times impressed on the parents the importance of keeping their children under the supervision of the family doctor.

DETERMINATION OF ALCOHOL IN URINE

At a meeting of the Society of Public Analysts, held on December 5th at Burlington House, Messrs J. EVANS and A. O. JONES described a method of determining small quantities of alcohol in urine, which was proposed as a chemical test for drunkenness. The urine was evaporated in a current of air, and the mixture of air and alcohol vapour was conducted into a strongly acid standard solution of potassium dichromate. The alcohol was oxidized to acetic acid, and the amount of the dichromate reduced was determined by adding potassium iodide and titrating the liberated iodine with standard thio-sulphate solution. After describing the apparatus designed for the purpose by Dr H. W. Southgate (see *British Medical Journal*, March 13th, 1926, p. 463), an outline was given of the experimental results obtained by Dr Southgate upon which the physiological interpretation of the amount of alcohol found in urine was based, together with an account of determinations by the authors of the extent to which alcohol was present in samples of urine from persons who had consumed known amounts of alcoholic beverages. The medico-legal application of the method was discussed.

Mr J. J. WIS answered criticisms which had been directed against his method of standardizing the iodine absorption of oils and fats. He showed that inaccurate preparation of the agent used had been responsible for the statement that theoretical values were not obtained with certain fatty acids; erroneous data had given rise to wrong deductions in other respects.

Mr A. SCOTT DODD, discussing the occurrence and determination of boron compounds in vegetable products, described investigations which showed that boron compounds had been found in a large number of dried fruits. The amount expressed as boric acid found in dried raisins and currants ranged from 110 to 260 parts per million, and, as regards miscellaneous dried fruits, from 40 parts per million in prunes to 300 parts per million in apricots and peaches. In fresh fruits the quantities ranged from 31 to 62 parts per million, corresponding to 220 to 550 parts per million in the dry substances.

Rebucius.

ESSAYS OF A SCHOLAR PHYSICIAN

As medicine is concerned with history and with science, with life and death, and with men and women, it easily leads the physician into the pleasant pathways of philosophy, and the philosopher, as opportunity offers, reveals himself, more or less abundantly, in the spoken or written word. It is this sequence of events which explains the appearance of Sir HUMPHRY ROLLESTON'S volume entitled *Aspects of Life, Life and Disease*. The book consists of thirteen personal studies, each one of which betrays an intimate acquaintance with the general and professional literature bearing on the debate and a capacity to make out of varied details a pleasing, instructive, and inspiring story. With the recital of many contributions from many sources is associated, too, the personal note that gives unity to the discussion and expresses the quality of the literary artist. That such a series of studies should be produced in the course of four or five years by an author whose professional and public responsibilities mean crowded hours, is an impressive demonstration of a love of literature and of a gift of expression that must command admiration, not perhaps altogether unmixed with a spice of envy. Sir Humphry Rolleston, however, has his assumed place with the goodwill of everyone, and the universal attitude towards his new volume will certainly be one of congratulation and of gratitude.

The subjects of the several essays vary widely, but common to them all is the thought that medicine is a part of life, and has active relations to other parts of life. Hence arises the necessity to define these relations and to secure accuracy of proportion and perspective if the (educational) values of medicine, as a mental and moral discipline are to be obtained for her disciples, and if the medical aspects of life are to find their rightful place in the discussions of the day and hour. Yet the essays are not purely or even mainly, on the academic plane, on the contrary, they are well in contact with daily interests, and the physician is not less prominent than the philosopher. Even that stern person the strictly practical man may find in these pages points which may well engage his attention, and possibly he may convince himself that the style and fashion of saving things has a value not altogether to be dismissed. It is sometimes said that medical writings are deficient both in lucidity and in literary achievement, but no such reproach attaches to Sir Humphry Rolleston's pen.

One of the essays—it appeared in our issue of October 9th, 1926 (p. 625)—is addressed to students and to newly qualified members of the profession, and is a careful analysis of the prospects offered in various branches of professional work. It applies itself to actual situations, and deserves careful consideration by those whose careers are opening before them. The author recognizes the value of experience in general practice and the desirability of cultivating at the same time expertness in a particular department. Such a combination, as he says, may develop the general practitioner "into an expert specialist" who may "set up in a big centre." This possibility has had some brilliant illustrations, but it may be doubted whether the present passion for a compulsory post-graduation curriculum and a "special diploma" will encourage such developments. In the same chapter Sir Humphry Rolleston subscribes to the view that medicine and surgery are unhappily divided, and that the desirable arrangement would be one of regional experts who would undertake all treatment, surgical as well as medical, in the departments over which they severally preside. He almost despairs of the future of the "general" physician and of the "general" surgeon. We venture to wonder whether the interests of medicine and of the public will be promoted by the evolution of groups of practitioners, each one of which will have a more or less pronounced diagnostic and operative bias in a narrow and particular direction. The care of individual organs and systems is no doubt excellent, but

we hope that someone will be left to look after the patient.

Related to the study of professional prospects are essays on success, the future of medical women, the medical aspects of holidays, and irregular practice and quackery, all of which make excellent reading and are characterized by an individual judgement which rests on thought and experience. More ambitious studies deal with old age with clinical variations of disease as recorded in history with the social and international consequences of diseases affecting rulers and other important personages, and with descriptions of diseases by medical men who have themselves been unwilling victims. In "Poetry and physic" recognition is paid to many disciples of medicine who have cultivated the muse, and in the "Medical aspects of Samuel Johnson" all who number among their friends the most engaging of literary companions will find notes both of interest and appeal.

The book is to appear in French as well as in English and we are more than content that our colleagues across the Channel are to have the opportunity of learning how literature and philosophy are cherished, amidst many competing professional demands, by an experienced and scholarly English physician.

POLIOMYELITIS

THE very severe epidemic of infantile paralysis in the United States in 1916 afforded a great opportunity for the study of the disease, and it is no doubt in part because of the experience gained then that Dr W. RUSSELL MACAUSLAND has been able to produce such a practical volume entitled *Poliomyelitis*. As surgeon to a big orthopaedic hospital the author's interests are largely concerned with treatment, but all aspects of the subject receive attention.

History, epidemiology, etiology, and pathology are well discussed in the opening chapters. The types of the disease are ably set out, with perhaps an over-emphasis on the rarity of polio-encephalitis, and diagnosis, both clinical and laboratory, is described. The rest of the book, over two thirds of the total bulk, deals with treatment in a thorough fashion. Treatment in the acute febrile stage and in the early paralytic stage is rightly emphasized, for in the opinion of the author "the majority of deformities can be avoided." It is fortunately possible, especially during an epidemic, to diagnose many cases of poliomyelitis before paralysis sets in, and for such cases the use of convalescent serum would seem to offer good chance of abating an attack. Unfortunately the results of serum treatment have varied greatly, and it is difficult to judge of its efficacy. Its use, however, has stimulated the early diagnosis of the condition. Treatment in the early paralytic stage comprises general symptomatic treatment, the prevention of development of deformity, and the restoration of muscle power. On each of these subjects Dr MacAusland has some wise things to say. After insisting on the prevention of deformity as the most important side of treatment he explains the causes of deformity under the following headings: muscle unbalance, ligamentous and tissue contraction, habit posture, static influence, and gravity. With a correct knowledge of these factors efforts at prevention can be carried out on scientific lines. On the treatment of the later stages the author is also very sound, his views on electricity will be welcomed, although he might have expressed his obvious views more strongly. "There is little need of electricity in the treatment of poliomyelitis." Muscle re-education by means of systematized exercises he considers of great importance for muscles in which some power remains, and very full details are given of the exercises suitable for various groups of muscles. Operative treatment completes this monograph, and is very fully described.

Apart from an omission to mention the use of cellulose splints there is very little about poliomyelitis which is not dealt with in this book. Dr Russell MacAusland has given us a comprehensive study, well illustrated and documented, and it should prove a valuable book to those concerned with this distressing malady.

WOUNDS AND INFECTIONS OF THE HANDS

Plais et Maladies Infectieuses des Mains,² by MARC IEELIN, deals with a subject of wide interest and importance, for in industrial areas wounds and infections of the hands are matters of daily experience.

Commencing with wounds of the fingers and of the hand and the simpler methods of their treatment, the author goes on to the more complicated and difficult problems involved where important tendons have been divided. The subject of tendon division is treated in considerable detail, and several novel methods are described. In discussing infections of the hand a full and clear description is given of the anatomy of the cellular spaces, a proper appreciation of which has revolutionized surgery in this difficult region. The after-treatment of infections, and of the disabilities which may arise is fully discussed, and the volume finishes with a discussion of plastic methods of reconstruction, considerable attention being directed to the very important reconstruction of the thumb.

The volume is admirably illustrated with photographs of actual cases, and with really excellent sketches. The latter alone should render the work invaluable to everyone who has to deal with the difficult problems of the surgery of the hand, and for this reason we can most strongly recommend it even to those medical men whose knowledge of French is very limited.

BIostatISTICS

THE substance of Professor RAYMOND PEARL'S *The Rate of Living*¹ will be known to a certain number of readers as it presents in an extended form, the thesis which he maintained in a course of lectures on experimental vital statistics at University College, London, in the summer of 1927. Professor Pearl, as head of the department of biometry and vital statistics in the School of Hygiene and Public Health of the Johns Hopkins University, has played a notable part in the application of modern statistical methods to medicine. In the volume now under review his concern is to advance the opinion that biostatistics is not merely an auxiliary to preventive medicine, but is "the sign, the symbol, and in some respects the very essence" of an independent branch of science, the biology of groups. His efforts have been directed to the extension by experiment of the existing body of knowledge regarding populations of living organisms, work in this field has been carried on in the biological laboratory at Johns Hopkins since 1919 with the fruit fly *Drosophila melanogaster* and its mutant forms, and *The Rate of Living* surveys the results of these investigations in so far as they relate to mortality. This has involved an elaborate series of studies

of the qualitative and quantitative aspects of the primary forces tending to bring about the decline or ultimate destruction of groups." Here, it is interesting to reflect, is the material with which the bulk of the world's political, social, and economic thought is concerned. The relationship between group biology and the sociological side of life was exemplified in the discussion on the falling birth rate in the Section of Medical Sociology at the Annual Meeting of the British Medical Association at Cardiff, in which Professor Clegg, dealing with the biological aspect, made several references to the work of Professor Pearl (*British Medical Journal*, September 15th, p. 477).

Those who are interested in the broad subject of population will find much that is suggestive in this book. Space does not permit any description of the methodology of these experiments, although this must appeal to those engaged on biostatistical work, nor is it possible to discuss the concepts of inherent vitality and total vitality, the former being that which the organism possesses as an implicit consequence of its pattern or organization, as demonstrated by the observable fact that organisms are able to perform vital actions in the absence of exogenous sources of matter and energy. Professor Pearl's conclusion is that in general, the duration of life varies inversely

as the rate of energy expenditure during its continuance. "In short, the length of life depends inversely on the rate of living." The author disclaims any pretence to conclusiveness in his work, which he prefers to regard merely as a stage in the development of research and as suggesting ideas capable of application and testing in many directions, notably in the field of human biology.

HAEMATOLOGY

DR ALFRED PINCY is a very industrious writer on *Diseases of the Blood*,² or diseases of the blood-forming organs, as he preferred to call the conditions in his *Recent Advances in Haematology*, the second edition of which was noted in these columns on June 30th, 1928 (p. 1114). The present volume is less ambitious in design, and is intended to supply the student and the practitioner with the outlines of immediate practical value, and to serve as an introduction to more elaborate works, which assume such an elementary knowledge. In the introduction the constituent cells of the blood are described and their ancestry discussed, the monophyletic and the polyphyletic views being illustrated by genealogies. A short account of the reticulo-endothelial system is also provided. The next two chapters deal with variations in the numbers of the white and red corpuscles respectively, and, as in the introduction and the glossary at the end of the volume, an explanation is given here of the numerous names which have been applied to the various cells of the blood. In the section on "leukaemia" the author points out that the blood is not a tissue at all, but a mixed secretion derived from various sources, that, "leukaemia" not being a suitable term, leucosis should be divided into myelosis and lymphadenosis according as the proliferating process is in the bone marrow or the lymphatic tissue. This overgrowth may or may not be accompanied by the appearance of their immature cells in the blood, so that leukaemic or aleukaemic myelosis and lymphadenosis arise. The forms of what are usually called myeloid and lymphoid leukaemia are then described under somewhat modified titles. In the chapter on "Some diseases allied to the leucoses" lymphosarcoma, lymphadenoma, and Mikulicz's syndrome are described, while myelomas and various forms of splenomegaly, such as Banti's syndrome, Gamma's, Gaucher's and Niemann's diseases, are dealt with later in separate chapters. The various anaemias, including aplastic, pernicious, chlorosis, and that of children, are summarized, and after dealing with the haemorrhagic diseases and polycythaemia there is a useful diagnostic chapter on symptomatic blood changes, the various diseases being arranged in alphabetical order. There are three appendices—on technique, blood groups and transfusion, and x-rays and radio-active substances, and the large amount of information so clearly set out in this book is further elucidated by the admirable illustrations, especially the coloured blood films.

HELEN HANSON

THE many friends of the late Dr Helen Hanson will welcome the memoir of her life,³ written by F. LOUISE ACRAS at the request of the executive committee of the League of the Church Militant. It is a compact little book which all who knew this most kindly and gentle of women will be anxious to possess, and it has the added attraction of several reproductions from portraits. The memoir is prepared from material provided by over one hundred of Dr Hanson's friends, among them those connected with her in medical work and various committees and associations. All her friends—those of old suffrage days, workers in the mission field and war workers—speak of her wonderful gifts, and particularly of her genius for friendship. Helen Hanson's childhood was an admirable preparation for her subsequent life's work, and at school she already showed the promise of a bright future. After graduation

⁴ *Helen Hanson*. By F. Louise Acras. With a foreword by Lady Barrett C.B.E. M.D. M.S. and an introduction by the Rev. G. C. Simpson D.D. London: H. R. Allnutt Ltd. 1928. (Demy. 8vo pp. viii + 119 illustrated 2 6d. net.)

from the London School of Medicine for Women she held various posts at home, and then entered the mission field. The three years she spent in India are described in some cheerful home-letters, and she would undoubtedly have remained there longer if she had kept her health. Her work in Belgium, Serbia, Malta, and Macedonia is touched upon, and her twelve years of school work under the London County Council is dealt with at some length. With her school inspections never degenerated into mere routine, and she found great interest and pleasure in the gradual improvement of the standard of health of the school children. A few extracts from Dr. Hanson's writings are included in the memoir, one of them, a little paper on "The study of Urdu," is most amusing, while the religious outlook, as revealed in a statement of belief found in some pages of manuscript after her death, is one of the most interesting things in the book. Every page in this memoir shows that her high courage, perennial gaiety, and selflessness were due to a deep sense of Christianity, revealed during her life by her good deeds, though but rarely by words. To portray this elusive personality, whose charm had something odd and rare in its quality, must have been difficult, but it has been accomplished successfully.

NOTES ON BOOKS

Dr. MOUTONNET has made a careful compilation representing his present views on vertigo entitled *Les Vertiges Labyrinthiques*. Vertigo is a symptom often presented to the neurologist or the otologist for elucidation and relief and often enough it is the only, or at any rate the predominating, symptom. This study should therefore be of some help to those specialists for the physiology of labyrinthine nystagmus, the various theories connected with it and the functional examination of the organ of equilibration are well reviewed. Differential diagnosis receives much space but the pathology of the labyrinth is less elaborately discussed and in the problems of treatment especially surgical treatment there is little practical help. The book is inclined to reflect the present tendency towards elaborate studies of nystagmus and functional tests which lend nowhere and to neglect the difficulty of affording the relief for which the patient cries aloud. It is, however, not purely academic and is a fairly balanced and scientific review, but the absence of references is a serious defect in a work of this type.

In the three years since Dr. PERCY HALL's book on ultraviolet ray therapy* was first published it has reappeared in three editions one new impression and two American editions, which is sufficient evidence of its popularity. In the present edition the author seems to have modified his opinion about quartz mercury vapour lamp and has added a good deal of recent information and several new pictures. The chart of electro-magnetic waves (reproduced by permission of the Council of the Royal Society) is an interesting feature of the book.

A Doctor's Wife (Maura Meighan) is the author of a useful little book on *Simplified Cooking and Invalid Diet*. It is intended to help nurses, mothers, and housewives who are needing recipes and advice on cooking based on the most up-to-date principles of dietetics. The author states that she has been largely guided by *Hitchcock's Food and the Principles of Dietetics* and that Dr. Robert Hutchison has read the MS. of her little work. The book is good, the directions are clear and practicable. Everywhere she insists upon the use of the thermometer in the practice of cooking otherwise the aim of the dietary will not be achieved. Some of the recipes we have tried, and they work out well. The one for raw cabbage, on page 96, is good. Those who dislike bread sauce may feel discouraged at reading. Bread sauce should never resemble bread poultice, and resolve to try again after the cook has read the directions of our author. Several special dietaries are set out as, for example, for chronic constipation, diabetes and fever, and a section is devoted to diet without milk and eggs.

M. VIRENQUE's booklet on the aesthetic surgery of the breast has appeared at an unfortunate time for such a publication, when the female sex appears to have entered into a conspiracy to disguise the fact that such an organ exists, and to reduce it to the smallest possible dimensions. The procedure described by M. Virenque is expressly designed to render more shapely and prominent such mammary as suffer from ptosis and it seems admirably adapted for the purpose. Our only criticism is that, in this country at all events, there is no demand for it.

The naïve egoism of Dr. A. I. SCHOFFIELD has overflowed into a volume three hundred pages long. *Behind the Brass Plate* is a book of rumour and gossip about men and women such as many people associate with the initials "I. P." Dr. Schofield, we gather, has rubbed shoulders with many distinguished personages. He has written letters to royalty, he has taken part in the birth of many movements. He believes in gifts of healing and in the existence of a "aurea", but he cannot abate spiritualism, and tells once more the story of M. W. T. Stead and the Yonkec entertainers. He disarms criticism by stating in his preface that he has simply set down such recollections of his life as his memory could recall, and that he has done so to amuse himself, as he is now debilitated from active life, and in the hope of lightening the hours of others similarly afflicted. His more or less veracious variis have the merit of vivacity.

PREPARATIONS AND APPLIANCES

A NEW SALICYLIC ESTER OF THE DIHYDROXANE SERIES

Some Clinical Results

Dr. A. GORDON WATSON (Bath) writes: During the past eight months I have given a new salicylic ester of the dihydroxane series (which may be abbreviated to SED) a clinical trial in rheumatic diseases at the Royal Mineral Water Hospital and in private practice and in a variety of injuries and diseases at the Royal United Hospital, Bath. It is neutral insoluble in water, but readily soluble in most solvents and fits used in pharmacy. The salicylic acid content is approximately 90 per cent but in spite of this high content it has so far been found to have no deleterious or irritating action on the skin. At first I used it in various strengths up to 50 per cent in an ointment, but latterly have used only 10 or 15 per cent.

As a pain-relieving application it soon showed its value. In April and May of this year I was collecting cases of sciatica for the medical conference held at Bath on May 10th and 11th and found that this ointment, applied by the patients at bed time, enabled some of them to sleep without the dose of aspirin previously required. Cases of rheumatoid arthritis obtained relief from pain and in one case marked swelling of the knee joints, which had resisted other treatment (mercuric ointment and potassium iodide ionization), quickly yielded to SED. In cases of generalized fibrositis and panniculitis I gave the patients whole body massage on days alternate to their mineral water baths, and am satisfied that it accelerated the cure in some cases.

On applying the pure drug to a raw surface—the result of a severe abrasion—there were no unpleasant results, slight warmth at first was soon followed by an anaesthetic effect. On this point I may mention that a patient who was using the ointment for sciatica found accidentally that it eased the pruritus associated with piles. It also quickly alleviates the itching from various skin diseases. A patient, aged 79 sent to me by a London physician as a case of generalized eczema which might provide clinical material for a dermatological clinic, was quickly relieved of all irritation, large patches of weeping eczema—on the palm of the hand, the arm, the abdomen, the labial folds, the anus and the area over the sacrum—all cleared up in three weeks, except one patch over the sacrum.

I found the 15 per cent SED ointment highly efficacious in the treatment of insect bites. Harvest bugs generally produce bullae on sensitive skins, if this substance is applied no bullae appear, irritation is reduced, and only a small papule remains as evidence of the insect's invasion.

In cases of injured joints swelling and pain are relieved, and a point of great interest is that where one would expect marked bruising, very little, if any, discoloration occurs. This action is so marked that I have asked some of my scientific friends to try to explain it by investigation of the action of this drug on the peripheral circulation. I believe that as the toxicity appears to be low it may be found useful as an internal remedy also.

Collective Investigation

INTO

THE TREATMENT OF VARICOSE
ULCERATION.

Report by

ARTHUR P. LUFF, CBE, M.D., B.Sc., FRCP,
CONSULTING PHYSICIAN TO ST. MARY'S HOSPITAL, HONORARY
DIRECTOR OF THE RESEARCH

THE British Medical Association, in connection with their collective investigation scheme, decided in 1928 to start with an inquiry into the treatment of varicose ulceration, and for that purpose two forms dealing with the questions to be answered were issued to those members of the Association who were willing to take part in the inquiry. In response 550 medical practitioners have filled up forms, and reports of 1,092 cases in all have been received. A large majority of the forms have been fully and carefully filled in, and great credit is due to those members who have made the returns for the trouble they have taken and the time they have spent in assisting in this inquiry. The answers to the questions and the information volunteered have now been collated, and the results are embodied in this report.

TABLE I—Sex Incidence of Varicose Ulceration

Number of cases	1 092
Males (percentage)	33.7
Females (percentage)	66.3

TABLE II—Age Incidence of Varicose Ulceration
(1 094 cases; age omitted in 8 cases of the total 1 092.)

Age	Percentage
20-30 years	2.3
30-40	10.7
40-50	24.7
50-60	31.9
60-70	21.8
Over 70 years	8.6

Remarks: This table shows that 56.8 per cent. of the cases commenced medical attendance between the ages of 40 and 60.

TABLE III—Percentages of Cases Healed at Various Ages
(No. healed 655; age omitted in one case of the total 656.)

Age	Percentage
20-30 years	2.6
30-40	13.0
40-50	28.5
50-60	31.4
60-70	17.9
Over 70 years	6.6

TABLE IV—Ratio of the Total Numbers of Cases at Various Decades to the Numbers Healed in those Decades

Decade	No. of Cases	Percentage Healed
20-30 years	25	68.0
30-40	116	73.2
40-50	268	69.7
50-60	348	59.5
60-70	236	49.5
Over 70 years	93	46.2

Remarks: This table shows that the expectation of healing is best up to 50 years of age, but declines steadily after that age.

TABLE V—Showing Age of Reporting for Treatment for Varicose Ulceration

(Age was given in 1 017 cases)

Age at Commencement	Percentage
13-20 years	1.8
20-30	13.8
30-40	28.5
40-50	30.9
50-60	15.6
60-70	7.1
Over 70 years	2.3

Remarks: This table shows that the majority of cases commence between 30 and 50 years of age.

TABLE VI—Occupation (given in 945 cases)

Occupation	Percentage
Domestic work	61.4
Other occupations involving prolonged standing	32.0
Farm labourer	2.9
Weaver	1.6
Gardener	1.2
Clerk	0.5
Motor driver	0.4

Remarks: The very small proportion of cases among farm workers and gardeners although their occupations involve prolonged standing, is interesting as showing the counteracting effect of constant muscular exercise in the open air.

TABLE VII—Suggested Causation of Varicose Ulceration

Suggested Cause	Percentage
Varicose veins	53.6
Injury	13.8
Phlegmasia alba dolens	4.0
Phlebitis	3.3
Prolonged standing	3.0
Not given	22.3

TABLE VIII—Relapses during Treatment

No. of Cases	Relapses
1 092	46.8 per cent.

TABLE IX—Number and Percentage of Total Cases and of Healed Cases, in which Rest in Bed or its Equivalent was Employed

	Number	Rest in Bed or its Equivalent
Total cases	1 092	614 cases = 56.2 per cent.
Healed cases	656	439 cases = 66.9 per cent.

The figures in this table show that out of the total cases that had rest in bed or its equivalent 71.5 per cent. appear among the healed cases.

Bandaging

This was an essential part of the treatment in 44 per cent. of the cases.

Strapping

This was an essential part of the treatment in 55 per cent. of the cases.

Local Treatment of the Ulcers

For the initial cleansing of the ulcerated surface various antiseptic fomentations were used, of which boric acid was the commonest. These have not been classified, but the principal applications or methods used for the treatment of the ulcers after cleansing are given in the following table.

TABLE X.—*Local Treatment of the Ulcers*

Application or Treatment used	No. of Cases in which used
Zinc preparation (generally a lotion)	249
Unna's zinc gelatin	164
Boric acid (generally a lotion)	159
Ultra violet rays	76
Injection of veins	60
Scarlet red ointment	37
Eusol	35
Carbolic acid	26
Removal of veins	25
Lassar's paste	25
Lead lotion	17
Ammoniated mercury ointment	11
Ichthyol	10

Various other methods of treatment (92 in all) were individually used in a very small number of cases, but as no useful deductions can be made from the results of their employment in so limited a number of cases, respectively they are not included in the above list.

Internal Treatment

Apart from the use of tonics, etc., the internal treatment mainly resolved itself into the administration of a calcium salt or parathyroid, alone or combined. A few medical practitioners report favourably on the internal administration of potassium iodide, but a large majority think it is only useful in syphilitic cases. Among the 1,092 cases included in this report potassium iodide was only administered in 61 cases.

Statistics as to the Effect of the Administration of Calcium Salts and Parathyroid in addition to the Local Treatment of the Ulcers

Among the 1,092 cases of varicose ulceration reported—

A calcium salt was administered in 102 cases.

A calcium salt and parathyroid were administered in 75 cases.

Parathyroid alone was administered in 58 cases.

Among the 656 cases in which healing occurred—

A calcium salt was administered in 35 cases.

A calcium salt and parathyroid were administered in 46 cases.

Parathyroid alone was administered in 13 cases.

The figures in the latter group show that among the 656 cases in which healing occurred 85.7 per cent had neither a calcium salt nor parathyroid administered, 7 per cent had a calcium salt and parathyroid administered, 5.3 per cent had a calcium salt alone administered, 2 per cent had parathyroid alone administered.

These percentages, in conjunction with the fact that out of the 235 cases in which a calcium salt, or parathyroid, or both, were administered, only 94 of the cases resulted in healing, would appear to show that the influence of these drugs on the healing of varicose ulcers is of minor importance, but that the advantage (if any) is slightly in favour of the combination of a calcium salt with parathyroid. A large number of medical practitioners state that after administering calcium salts as a routine method of treatment they have abandoned them as useless.

Opinions as to the Value of Calcium Salts and Parathyroid, alone or combined, in the Treatment of Varicose Ulceration

The specific question on Form 2 bearing on the above was answered by 428 medical practitioners as follows:

58.7 per cent found no benefit from their use
21.0 per cent believe them to be of some benefit
19.3 per cent never use them

Opinions as to Preventive Treatment of Varicose Ulceration

The specific question on Form 2 inviting the experience of medical practitioners as to what conclusions they had arrived at with regard to the preventive treatment of

varicose ulceration was answered by 450 practitioners as follows:

43.1 per cent recommend bandaging
20.6 per cent recommend rest
14.6 per cent recommend removal of veins
12.0 per cent recommend injection of veins
8.4 per cent recommend use of the elastic stocking
3.0 per cent recommend avoidance of use of garters

Results of Local Treatment

Of the 1,092 cases which form the subject of this report the ulceration was healed in 656 cases. In 147 of these cases the local application or treatment was employed in so small a number of cases, respectively, that no reliable deductions can be drawn as to the utility of the method of treatment. The following table gives the applications or methods of treatment used in 507 of the cases that were healed with the respective results.

TABLE XI

Local Treatment	No. of Cases in which Used	No. of Cases Healed	Percentage of Cases Healed
Removal of veins	25	25	100.0
Ultra violet rays	76	70	92.1
Injection of veins	60	55	91.6
Unna's zinc gelatin	164	117	71.3
Lead lotion	17	10	58.8
Lassar's paste	25	14	56.0
Carbolic acid	26	13	50.0
Ichthyol	10	5	50.0
Boric acid (lotion generally)	159	77	48.4
Ammoniated mercury ointment	11	5	45.4
Scarlet red ointment	37	15	40.5
Zinc preparation lotion generally	249	91	36.7
Eusol	35	10	28.5

A number of medical practitioners state that failure in healing was attributed to the refusal of patients to rest during treatment. This especially applies to the cases treated with Unna's zinc gelatin, among which the percentages of cures would probably have been higher if the advice to rest had been carried out.

Length of Time that the Ulcers had Remained Healed at the Date of Reporting

Out of the 656 cases in which the ulcers were healed the periods for which they had remained healed are given in 523 cases. A number of the cases were reported on soon after healing had occurred, so that the periods vary from a few weeks to some years. It is not considered desirable to occupy space with the tabulation of all these periods, but the average time over which the ulcers had remained healed in the 523 cases works out at thirteen months.

Conclusions and Recommendations as to the Most Reliable Methods of Treatment of Varicose Ulcers

Table XI shows that the best results were obtained respectively by (a) removal of veins, (b) the use of ultra-violet rays, (c) injection of veins, and (d) the application of Unna's zinc gelatin.

With regard to the choice of removal or injection of the veins, I am of opinion, from the perusal of the returns, that obliteration by injection is the simpler and safer procedure. This is also the opinion of G. H. Colt who, writing on the results of injection of the veins with salicylate saline solution, states that he obtained results which were so much better than were possible by laborious and somewhat risky operations that in his opinion operation seems to be no longer justifiable except in certain very isolated cases.

Whether a quinine or salicylate solution is preferable for injection remains to be settled, and it is very desirable that further inquiry should be made to determine this point. G. H. Colt considers that the larger volume of

the salicylate saline solution is more manageable than the smaller injection with the quinine solution, and is attended with negligible risk and little inconvenience. In addition he points out that quinine sometimes produces blindness, and that the risk is said to be about 1 in 1,600. R. M. Handfield Jones¹ states that, after experiencing unsatisfactory results from the use of quinine and urethane, he has confined his treatment to the injection of sodium salicylate in varying strengths of from 20 to 40 per cent.

Ultra-violet rays give excellent results, but they require administration by skilled operators, as a definite technique has to be employed in their successful use, and the dose requires to be varied according to the septic condition of the ulcer, the nature of the edges, and the condition of the surrounding skin. It would appear that in the majority of cases this treatment could not be carried out by the medical practitioner, but would have to be done in hospitals possessing the necessary installation and skilled operators.

The following are the conclusions at which I have arrived as the result of this inquiry.

1 *Treatment*—That in order to obtain the best results it would be advisable for the medical practitioner to limit the treatment of varicose ulceration to two procedures. The first is injection of the veins in combination with the use of Unna's zinc gelatin for the local treatment of the ulcer, the second is the use of Unna's zinc gelatin alone if injection is refused, or for other reasons cannot be carried out. It should also be borne in mind that treatment by ultra violet rays appears to be very reliable, provided that the proper administration of these rays is available.

2 *Prevention*—As the true varicose ulcer is the result of varicose veins it would appear that the rational method for the prevention of such ulceration is the obliteration of the affected veins, or the removal of them by operation. Of these two procedures it appears that obliteration by injection is both the safer and the easier one. If it is not possible to carry out either of these two procedures, then support of the veins by suitable bandaging should be employed.

RHEUMATISM IN RELATION TO INDUSTRY

A LECTURE on rheumatism in relation to industry was given at the Royal Institute of Public Health, on December 5th, by Dr Fortescue Fox, with Sir A. Stanley, Chairman of the British Red Cross Society, in the chair. The lecturer said that the first international conference on industrial rheumatism, convened by the International Society of Medical Hydrology, was held in London in November, 1925. Another conference, at which reports from eight countries were presented, took place at Buxton last October to frame the organization of an international league against rheumatism. In the three years separating these events the problems of rheumatism had been seriously discussed in the northern countries of Europe, and representative national societies had been formed to collect information to encourage and co-ordinate the existing work carried on, often in isolation, both for investigation and treatment of rheumatic disease, and to formulate proposals for the development of this work on approved and practical lines. Steps were being taken in England to form an association with the same objects, in succession to the British Committee on Rheumatism of the International Society of Medical Hydrology.

Proceeding Dr Fortescue Fox said that he had long held that arthritis varied both in character and severity at different periods of life. The rapidly progressive deforming arthritis of young adults, the "climacteric" arthritis of middle life (in both men and women), and the degenerative or local arthritis of age formed three definite clinical groups and were practically different diseases. It was unfortunate and confusing that the same name, "rheumatism," should be given to "rheumatic fever," which might well be called "cardiac fever" from its close connexion with heart affection, and to these insidious and chronic crippling diseases of older people, different forms of arthritis, none of which affected the heart. But there was some excuse

for it, because all the acute and chronic "rheumatisms" were related to definite external causes. They were all, in short, climatic and geographical diseases, diseases of zones or regions of the earth like tropical diseases.

The normal body showed a defensive reaction to the impressions of cold and damp, but there was good reason to think that in persons with "rheumatic liability" this reaction was defective, and might be entirely absent. The same reactions were also defective in infancy and old age, and hence external warmth and shelter were necessary to protect people at the extremes of life from the ill effects of uncompensated cold. The hot vapour baths used by northern nations from remote times were an endeavour to maintain, and perhaps restore, the reaction to cold—in short, a preventive and curative regimen in those bleak and inclement regions. Another external provocative of rheumatic disease was infection, which made havoc in persons with low resistance. But disease germs were relatively harmless in a healthy body. Sir George Newman had given warning of the necessity of "frustrating the activity of organisms within the body." It was well to get rid of these organisms, but was there any guarantee that where one weed had grown another might not grow? The radical treatment of rheumatism was to remove the rheumatic liability. To attempt to remove the organisms of diseases from the body without at the same time fortifying its resistance to invasion was like pumping a waterlogged ship without stopping the leak. It was good to remove an obvious danger, but it was better to make the ship seaworthy. Another cause of rheumatism was poisoning from within from abnormality of the body fluids, including suboxidation, the retention of waste products, and endocrine disorders.

Rheumatic disease, like most other diseases, must be attributed to the co-operation of external and internal causes, or to external causes acting upon a weakened body. Hence, many medical thinkers no longer spoke of a cause of disease, but of the "constellation of causes." The variety in individual cases and in groups of cases no doubt depended on the many possible combinations of external and internal causes, and hence the necessity in treatment of the study of individuals.

Apart from surgical procedures very little had been done to provide special treatment for rheumatic diseases. In spite of the burdens it laid upon industry, there were as yet no special departments for rheumatism. Fine work had been done at the English spas, but this only touched the fringe. In Continental countries town clinics for physical treatment had been established by the friendly societies to supplement the work of the spas. They dealt with forms of chronic disease in the industrial population for which the hospitals were unable to provide. The great physical forces—heat and cold in air and water, light, electricity, friction, and movement—were true physical remedies, and the body responded to these remedies by a wonderful series of reactions affecting both the tissues and the organs. The universal belief and experience of mankind had been amply justified by physical and physiological discovery, they now knew that all diseases which had a physical factor in their causation were properly treated by physical remedies.

In conclusion, Dr Fortescue Fox said that the clinic for rheumatism to be set up by the British Red Cross Society would be completely equipped for physical treatment and clinical investigation. It had been designed to treat 500 cases and upwards every day. The ground floor was devoted to medical baths, including pools and douches and vapour and thermal mud, with and without frictions and movements. In other departments, light, radiant heat, electrical currents, ionization, and diathermy would be used, and there would be special appliances for measurements and investigations. It was proposed that this assemblage of physical methods should be made available for suitable cases from the general hospitals. It was not claimed that clinics of this character would meet the whole need for these difficult rheumatic affections, but they would provide early treatment near the people's homes, and serve as diagnosis bureaux, and also for the demonstration and teaching of methods which were still comparatively unfamiliar.

British Medical Journal.

SATURDAY, DECEMBER 22ND, 1928

TREATMENT OF VARICOSE ULCERATION

In May, 1926, the Ministry of Health submitted to the British Medical Association a scheme for collective research by insurance practitioners, and in January, 1927, it outlined definite schemes for such investigations to be conducted by the Association and Ministry working in collaboration. The Ministry proposed that these inquiries should be undertaken by general practitioners engaged in the insurance medical service, and should be confined to insured persons. A special research subcommittee appointed by the Council of the Association to consider these proposals reported in due course to the Science Committee. Its recommendations were (1) that any scheme of research must be voluntary and unpaid, (2) that it must not be restricted either to insurance practitioners or to insured persons, (3) that it should be organized by the British Medical Association through the Divisions, and (4) that the subjects chosen for inquiry should be of such a nature that they could be treated in a simple manner. The subcommittee expressed the opinion also that a medical adviser to correlate the returns and advise the practitioners taking part would be necessary for a successful investigation. Following these preliminaries a discussion took place between the subcommittee and representatives of the Ministry of Health, when the Chief Medical Officer, Sir George Newman, cordially welcomed the suggestions outlined above. Eventually it was decided to initiate two concurrent inquiries—one into the treatment of varicose ulceration, and the other into the after history of patients who had undergone the operation of gastro-enterostomy.

At this stage the Association applied to the Medical Research Council for financial assistance to pay a medical adviser to control the investigations, but the Council replied that it was not convinced that a scheme of collective inquiry was likely to give useful results except where some definite new clue had been obtained by intensive research of another kind, and where new evidence was sought along a line precisely indicated. The members of the subcommittee, however, were convinced that the united experience of doctors engaged in a properly conducted collective investigation ought to yield data of great clinical value.

The first inquiry has now been completed, and its results are set out in the report published at page 1144 this week. The Council of the Association has been extremely fortunate in securing as Honorary Director of Research Dr. A. P. Luff, consulting physician to St. Mary's Hospital, Home Office Analyst, and a member of the Food Preservatives Committee appointed by the Ministry of Health. We feel that it will in no way detract from the valuable and accurate information that practitioners throughout the country have given if we say that Dr. Luff's work in correlating and presenting the case for them is above all praise, and has contributed in a high degree to the success of the investigation. The names of two other members of the special subcommittee should also be mentioned for the encouragement and support they gave to this piece of research—Dr. C. E. Douglas (who acted as chairman) and Professor W. E. Dixon.

Varicose ulceration is a common disease, and every general practitioner is required to treat it. It causes not only pain and discomfort, but is responsible for a very great deal of disability, especially among women. The treatment is tedious, the results are often disappointing, and relapse is common, so that it was most desirable to collect information with regard to the best form of treatment, particularly as it was known that some practitioners were more successful than others in their results. One of the most remarkable points brought out by this inquiry was the great variety of methods employed at the present day for the alleviation or cure of a single well defined condition. Scores of different local applications appeared to be used by individual practitioners, zinc preparations of one kind or another far outnumbering all the rest. Dr. Luff's report, which reviews in detail the statistical side, will be studied by our readers everywhere with the greatest interest. It has established the value of a collective investigation of this kind as an important branch of practical as opposed to academic research. Dr. Luff, in his conclusion, says that the investigation shows that in order to obtain the best results "it would be advisable for the medical practitioner to limit the treatment of varicose ulceration to two procedures. The first is injection of the veins in combination with the use of Unna's zinc gelatin for the local treatment of the ulcer, the second is the use of Unna's zinc gelatin alone if injection is refused, or for other reasons cannot be carried out. It should also be borne in mind that treatment by ultra violet rays appears to be reliable, provided that the proper administration of these rays is available." Besides these positive findings it seems worth while to emphasize the point that the once widely used treatment of varicose ulcers by administration of calcium salts, with or without parathyroid extract, has completely failed to establish itself as a trustworthy therapeutic measure.

The report conclusively indicates the best treatment prevailing at the present time for a known pathological condition, and this information has been derived from the collective evidence of a great number of general practitioners. It may be accepted that those who took part in the investigation, numbering 550 in all, belong to the keenest and most observant class of doctors—men and women anxious to assist not only their patients, but their colleagues as well. If the results of the inquiry are made the basis for future treatment of this widespread condition it is obvious that a large amount of disability will be prevented, with consequent advantage to everyone concerned. Among the economic gains will be a saving in the drug bill. We venture to suggest, therefore, that if practitioners act upon the results of their own experience in this collective investigation they will be assisting not only their patients and themselves, but their country.

LIVER TREATMENT OF PERNICIOUS ANAEMIA

Progress in therapeutics, though often slow, is occasionally accelerated in a way which borders on the dramatic. Had one been asked two years ago to compile a list of those tragic diseases which at the very moment of first diagnosis foretell inevitable and speedy death, pernicious anaemia would certainly have had a prominent place, to day there is probably no disease in which so confident a promise can be given of a complete and comparatively rapid recovery.

Writing on the subject of the liver treatment of pernicious anaemia in the early part of the present year we expressed the opinion that in attempt to draw conclusions as to the permanence of the good results thus obtained would be premature. Strictly speaking some degree of caution is still necessary to-day, but it cannot be denied that the uniform and widespread success of the treatment which we owe to Minot and Murphy has been such as to justify the expectation that results so consistently gratifying in the initial stages would not disappoint us in the end. Hopes that it were gaining ground were perhaps a little diminished by some observations made by Price Jones at the summer meeting of the Pathological Society of Great Britain and Ireland: he suggested that even after the apparent return of the blood to normal there might yet be a considerable excess of the abnormally large cells present in the blood stream and that the cures were not really so complete as had been supposed. Similar observations have since been published in a recent paper by Davidson and McCune¹ but, as Price Jones recognized, the available data as to the size of the cells in normal and healthy individuals are as yet too incomplete to enable us to draw any final conclusions in the matter. Whatever the outcome of these investigations may be their bearing is chiefly on the nature of the pathological process underlying the disease and not for the moment on the practical business of therapeutics. From experience already gained we know that once the anaemia has completely disappeared the amount of liver that the patient must continue to take varies with the individual: that in some patients it may be reduced considerably while in others even a small diminution is followed by deterioration in the blood condition and that the only recorded cases of relapse have been in patients who have reduced the liver diet too much or have abandoned it altogether.

So complete, indeed, has been the success of liver treatment that interest therein has largely passed from the therapeutic results themselves to the light they throw on our ideas in general about the etiology and pathology of the condition, and, in particular on the possible need for relaxing somewhat the stringency of the criteria by which the disease is to be diagnosed. No new theory of the causation of pernicious anaemia has been established, but it appears that the conception of a primary haemolytic lesion is gradually being discarded. Those who look on the intoxication from the alimentary canal as the essential etiological factor have been forced to the hypothesis that the toxins elaborated in the intestine act either by interfering with the liver function preventing the formation there of some substance which is essential for the maturation of the red cells or by inflicting direct damage upon the patient's marrow. When considering the part played by the liver it is well to remember that kidney diet is quite as efficacious as liver: any hypothesis based on the supposition that liver diet merely provides some substance which a diseased or inefficient liver is incapable of producing must clearly be received with caution.

Diagnosis, too, has been not a little affected by careful study of the results of liver treatment. Minot, quite early in his work suggested that any failure to respond to liver treatment was to be taken as an indication that the patient concerned was not in fact suffering from pernicious anaemia—a suggestion that was apt to raise a smile on the face of the sceptic who had then had no personal experience of the method. Careful review of a large series of cases however goes

far to confirm Minot's suggestion, and it is found that in almost all cases which are refractory some atypical signs can be detected which make an alternative diagnosis at least possible, if not probable. On the other hand, certain patients in whom some cardinal sign is absent may perhaps be more readily placed in the group of true pernicious anaemia if they show a characteristic response to liver therapy. Among such cases we may include the one recorded by Dr Stanley Davidson in our present issue (p. 1123), in which the typical achlorhydria was lacking. There is a general tendency to insist rigidly on the absence of achylia as a bar to the diagnosis of pernicious anaemia, and Heath² excludes from his list of pernicious anaemia cases one which would certainly have been included but for the presence of free hydrochloric acid in the gastric contents. Other similar cases have been recorded in the past, and however freely we may whittle these down by rather ruthless criticism, there still remains a residue which withstands all attack in the future a typical response to liver diet may perhaps be admitted as a *last line of argument* in support of the diagnosis.

During the past year a number of liver extracts have been put on the market and have proved their worth as a substitute for whole liver. A good many workers seem to have gained the impression that whole liver, when it can be obtained and is well taken gives in some indefinable way rather better results than the extracts, these clinical impressions may be well founded, but in so far as the results are open to accurate measurement no superiority of whole liver over liver extract has been demonstrated. This observation applies also to the interesting investigation recorded by Dr Janet Vaughan³ on the increase in weight of patients on liver diet. In her series all the patients gained weight, some of them to a remarkable degree and with great rapidity, whether this has anything to do with pernicious anaemia, or whether it is a wholly independent phenomenon, remains to be seen, it may be that here we have a therapeutic indication of some significance in quite another direction.

IMPERIAL BUREAUX

Our readers will remember that at the Imperial Agricultural Congress held in London at the end of last year, among many constructive recommendations made for the fostering of co-operation in agricultural research throughout the Colonies and Dominions was one for the creation of imperial bureaux in this country. The most important of the various functions of such bureaux was to disseminate the results of research in all parts of the Empire, and in other ways to co-ordinate the work of the various research stations at home and abroad. This recommendation has quickly borne fruit, and last week it was officially announced that eight such imperial bureaux were to be immediately formed in Britain—namely Soil Science (Rothamstead), Animal Nutrition (Aberdeen), Animal Health (Weybridge), Animal Genetics (Edinburgh), Agricultural Parasitology (St Albans), Plant Genetics, Non-herbage Plants (Cambridge), Plant Genetics, Herbage Plants (Aberystwyth), and Fruit Production (East Malling, Kent). While the main function of these new organizations is to foster agricultural research, the collection and dissemination of current information will affect other branches of applied science, and a number of these stations will have direct bearings on medicine. The Imperial Bureau of Animal Health will be established at Weybridge at the veterinary laboratory of the Ministry of Agriculture,

¹ Heath *Journ Amer Med Assoc* xci 13 p 828

² Vaughan *Lancet* May 26th 1926 p 1063

³ Davidson and McCune *Lancet* November 17th 1928 p 1014

under the directorship of Mr W H Andrews, D Sc, M R C V S. The laboratory was established in 1914 under the late Sir Stewart Stockman, and is mainly concerned with the diagnosis and control of the contagious diseases of animals. It is able to devote some time to research, in recent years notably on foot-and-mouth disease, poultry diseases and similar subjects. The Imperial Bureau of Animal Nutrition is to be established at Aberdeen at the Rowett Research Institute under the directorship of Dr Orr. This institute, although begun in 1914, was not opened until 1922. Its object is to obtain information which will enable animals to be fed and handled so as to produce the maximum amount of human food with the minimum cost. It has already produced valuable results, especially in relation to vitamins, mineral metabolism, and so on. Both of these bureaux are important from their own point of view, but they are also important from their relationship to human health and human nutrition. Much publicity has been given in recent years to comparative medicine, and there is now a growing appreciation of the debt which human medicine owes to animals. Accordingly the collected current information on these subjects should be highly informative to medical science in general. The Imperial Bureau of Agricultural Parasitology will be established under the directorship of Professor R T Leiper of the Institute of Agricultural Parasitology. This institute, an integral part of the London School of Hygiene and Tropical Medicine, is located at St Albans, and there is no need to emphasize the importance to medicine, as well as to agriculture, of much of its work in the sphere of comparative parasitology. Few of man's parasites are exclusively human, and information as to the behaviour of these forms and their relations in animals is of fundamental importance to a complete understanding of how they affect man. Accordingly the collating of all the available current literature is of more than passing importance. In addition to the recommendations mentioned above, the Imperial Conference favoured the establishment of a chain of research stations throughout the tropical parts of the Empire. The station at Addis Ababa in East Africa, as well as the recently projected station in Queensland, will be included in this scheme, and last week the Government of the Union of South Africa approved of the inclusion of their veterinary research station at Onderstepoort also. This laboratory, though not strictly tropical, includes many of the more important tropical veterinary diseases within its purview. Its previous work, under the directorship of Sir Arnold Theiler, has been of a very high standard, and has included researches into botulism, mineral deficiencies, tick-carried diseases, and similar subjects of considerable interest to medicine generally. Its future work will presumably embrace even more varied subjects, and its value to tropical research be accordingly enhanced.

PLAGUE IN CHINA

With the possible exception of Hong-Kong, where there were six cases last spring, the greater part of China would appear to have escaped plague during 1928. While India and French Indo-China are widely invaded, there have been no recorded epidemics of this disease in South and Mid-China during the course of the year. It is from the northern endemic centre of Outer Mongolia that plague, helped by the recent extension of new railway lines, has spread down through Inner Mongolia to the province of Manchuria. These railways have opened up the land for cultivation, mostly by poor immigrant farmers coming from Shantung, who live under crowded and often insanitary conditions. Early last August suspicious deaths occurred in the region of a place called Tung Liao, 400 miles from Harbin, the big Russo-Chinese city in North Manchuria, and investigations by Dr Wu Lien-Teh and Dr J W H

Chun, both Cambridge graduates, revealed the presence of *Y. pestis* in femoral buboes. Probably, as was the case in 1927, some few isolated foci had been smouldering on the Mongolian frontier since early summer, and the disease had later taken on an active form. It is interesting to note, as showing the activities of the League of Nations Health Committee and its Far Eastern Health Bureau, that it was in response to telegraphic inquiries from these bodies in Geneva and Singapore that Dr Wu, head of the North Manchurian Plague Prevention Service, set out for Tung Liao to investigate on the spot. About the same time telegrams were received from the Mongolian and Russian medical departments of Uiga requesting the Plague Service at Harbin to send 3,000 doses of vaccine and 10 litres of serum to deal with plague conditions there. These supplies were at once forwarded by Siberian railways to Verkhneudinsk, and thence by aeroplane to Uiga, the remote capital of Mongolia. By the end of September over 400 deaths had been recorded at Tung Liao, and protective inoculation was conducted on a wide scale, in addition to antiplague serum for treatment of the sick. House-to-house visits for detection of cases and isolation of contacts were largely responsible for the dying down of the epidemic, during which it was estimated that 92 per cent of the cases ended fatally. Experiments in the line of ascertaining whether human ectoparasites can convey plague infection have tended to prove this to be the case. Drs Wu Lien Teh and Pultzer, working in Harbin, successfully inoculated guinea-pigs, which died on the ninth day showing all signs of subcutaneous plague after having been bitten by human *Pulex irritans* (two insects after twenty-four hours' starvation), and this discovery of direct infection by the human flea has rather complicated the earlier Indian theory of bubonic plague being only developed through the rat-flea. Perhaps the fact that the habits of the villagers in sleeping on unswept "kangs" (heatable hollow platforms) with their clothes off may explain the unusual prevalence of axillary, cervical, and septicaemic cases. In the severe North Manchurian epidemics of 1911 and 1921, outbreaks which had arisen from a tarabagan (Siberian marmot) showed a strong tendency to develop pneumonic features. In the neighbouring province of Shansi a serious outbreak of bubonic plague occurred during October, about seventy-five miles west of the provincial capital, Tai Yuan Fu. It affected eighty-four villages, and by October 28th it was estimated that there had been over 2,000 deaths. The local Chinese seem to have been unable to cope with the situation, and finally dispatched troops from Tai Yuan Fu for the purpose of drawing a cordon round the infected area and preventing the further spread of the epidemic. Since autumn there have been famine conditions in widespread areas of North China, these result in lowering the body resistance and in the huddling together of the people, which are favourable factors for the spread of epidemics. China is still a long way behind in the matter of proper and adequate medical supervision, but this should come in time. The Chinese people have on previous occasions given proof of their responsiveness to Western methods of dealing with epidemics, and when scientifically trained doctors are available in much greater number than heretofore, progress in public health measures will be welcomed by the natives. The epidemic in Shansi Province was officially stated to be of bubonic type, and it was also reported to be dying down. On this ground offers of help in antiplague measures, made by foreigners, were declined. But on November 14th a telegram was sent from Dr Curran of the American Board Mission in Fenchow (Shansi) stating that there is now an outbreak of pneumonic type, and asking for further help to combat this. Doctors from the American and the English Baptist Missions are proceeding to the area of the outbreak.

THE TERCENTENARY OF MALPIGHI

THE year which marks the tercentenary of the publication of *De Motu Cordis* marks also that of the birth of Marcello Malpighi, Italian physician and philosopher. Founder of histology, greatest of microscopists, experimental physiologist, pioneer of iconographic embryology, patient and devoted physician, Malpighi lives in the history of medicine not only as a genius who effected a revolution in scientific thought and method, but as a most lovable personality. The plates accompanying his Royal Society memoirs are an indication of his quality as an embryologist the *De formatione pulli in ovo* and *De ovo incubato*, of his powers of observation and description. His name, as histologist, has been preserved in the Malpighian layers of the skin in the Malpighian bodies of the spleen, and in the Malpighian plexus of the kidneys, tufts, and capsules of the kidneys. In *De viscerum structura* he gave the first account of the lymphatics and splenic nodules of lymphadenoma, the disease later associated with the name of Thomas Hodgkin. Above all, he demonstrated that the capillary anastomosis between arteries and veins of the lungs (which to Harvey was a conceptual hypothesis) was a histological reality. The tercentenary of Malpighi was celebrated in the Section of the History of Medicine of the Royal Society of Medicine on December 12th by a lecture by Professor Franchini, director of the Institute of Tropical Diseases in Bologna. As becomes a fellow Italian and a son of Malpighi's own university, Professor Franchini made rather liberal use of high colours in portraying this pioneer, but he succeeded in giving a vivid picture of the state of science in seventeenth century Italy. This was a time when science was fighting at close quarters with ignorance and prejudice. When Malpighi was an infant Galileo was before the Inquisition, and the fires that burnt Michael Servetus in Geneva and Giordano Bruno in Rome had not entirely gone out. Persecutions odious though petty were inflicted upon Malpighi himself. He shared the obloquy attaching to those who practised dissection which was judged to be desecration of the dead. His chief enemies, however, were his fellow scientists, who broke his microscopes, wantonly destroyed his valuable manuscripts, and may even have set fire to his house. He bore these persecutions in silence and with magnanimity. When he removed from Bologna to Messina where for four years he was professor of medicine the persecution followed him, and eventually caused him to relinquish his chair. The Church seems to have been his protector at all events, he enjoyed the patronage of a cardinal, and in 1691, three years before his death, he became private physician to Pope Innocent XII. Not was it the general populace who made his scientific pursuits so difficult, for during his lifetime they reared a monument to him in his own city. He had many powerful friends, one of them Borelli, a distinguished mathematician and disciple of Galileo, in whose house at Pisa Malpighi practised his anatomical dissections and researches. In this house he made the discovery of the spiral structure of the cardiac fibres, a discovery which Borelli also claimed to have made. Returning to Bologna, he followed many lines of study, including the mechanism of respiration, the nature of the blood—whose red corpuscles he once described as "fat globules looking like a rosary of red coral"—and the structure of the brain. His work became known far beyond the confines of Italy. To the Royal Society of London he contributed a striking piece of research on the silkworm, and later other work in what would now be described as embryology and biology. He worked upon the embryology of the chick, studied the porcupine, the lizard, and the frog and made innumerable researches upon the anatomy of plants. Giving admirable accounts of germination. Professor Franchini quoted Haeckel as stating that only Lamarck and Wolf in the

eighteenth century, and Darwin and Muller in the nineteenth, could rank with Malpighi, the naturalist and philosopher. "In every observation of his," said the lecturer, "appeared the genius which understood clearly what was seen and went straight upon its aim. He did not pay attention to ridiculous disputes, nor lose time in useless scholastic arguments. He was a diligent student, a model of prudence, magnanimity, and modesty in an environment often hostile." Professor Franchini declared that if the writings of Malpighi had not fallen for two centuries into an unmerited oblivion we should see his name connected with a great number of tissues and functions which he was the one really to discover and describe. His manuscripts have been collected in sixteen thick volumes in the library of the University of Bologna, and there are others in Rome and elsewhere. Marcello Malpighi's latter days were rather pathetic. Professor Franchini described how he was summoned, an ill and tired man, to Rome to receive the title of pontifical head physician. In Rome the ruling passion was still upon him, and he continued many botanical, zoological, and chemical observations until he was struck down by cerebral hemorrhage. He got better, but shortly afterwards he was again stricken, and not the most energetic treatment could revive him. He died in the Quirinal Palace on November 28th, 1694, at the age of 66. A few weeks ago, by permission of the authorities, the tomb and coffin of Malpighi were opened. A skull of large size was found, well preserved in the upper part the temporal bone on one side had been, it appeared, cut away. Other bones were found, chiefly of the legs, but there were no documents or other objects in the coffin.

ULTRA VIOLET LIGHT IN THE HOME.

ON October 13th we published the papers read by Professor Dixon and Dr. Heald before the Section of Radiology and Physio-Therapeutics at Cardiff, and emphasized in a leading article the risk to the public arising from the administration of treatment by radiation and electricity at the hands of unqualified practitioners. Any doubt as to the need for that warning should be dispelled by perusal of the report in the *Times* of December 13th of a lecture on the applications of electricity to medical practice, delivered by Mr. G. G. Blake at the Royal Society of Arts before a meeting presided over by an eminent man of science, Sir Oliver Lodge. Mr. Blake seems to have convinced himself that not nearly enough unqualified persons are administering ultra-violet ray treatment. His ideal is an installation in every home, to be used by the members of the family upon themselves or upon each other. With reasonable care, he holds, the treatment is harmless, its administration requiring only a little common sense. He admits, indeed, that over exposure may produce the "familiar sunburn so prevalent at the seaside in holiday time," and that it is necessary to protect the eyes and the back of the head from the rays. But, having said this, and thrown out a suggestion that when lassitude follows exposure to ultra-violet light it is as well to stop treatment for a while, he feels apparently that he has issued warnings enough. The full text of the lecture is not before us, but in the newspaper report there is no word about the light allergy following over-dosage, described by Professor Dixon in his paper, nothing about the fact that treatment may be contraindicated in the presence of arterio-sclerosis, renal disease, some forms of heart disease, and phthisis. Nor is there any hint that the assessment of dosage—which seemed so easy in the early days of ultra-violet therapy before anybody knew much about it—is now recognized to present a difficult technical problem, to be solved only by those who have had adequate training. Medical men and women are not inclined to dismiss the dangers of ultra-violet

therapy in this light hearted fashion. Perhaps as individuals with a highly developed sense of responsibility they are unduly timid, but one may recall in this connexion an aphorism of Mr. Bertrand Russell's to the effect that when on any subject all the experts are agreed, the opposite opinion cannot be held to be certain. Anyone who said in public that every household ought to keep a stock of arsenic or strychnine for self-administration by the light of 'common sense' would not be taken very seriously, except perhaps by the police. But a manufacturer of arc lamps, or a lecturer in John Street, Adelphi, can give analogous advice in relation to actinotherapy without protest except in a medical journal. There may be something to be said in favour of trusting certain highly intelligent persons to administer ultra-violet light to themselves under medical directions, we may even grant that others, so robust as not to need this treatment at all, may indulge in self-irradiation without coming to much harm, but we cannot too strongly condemn the suggestion that arc lamps may be installed in every household and used with benefit and without appreciable risk by all and sundry.

MEDICAL SOCIETY OF LONDON

The programme for the second half of the current session of the Medical Society of London is now before us. The first item is a pathological evening on January 14th, commencing at 8 o'clock. The following general discussions have been arranged: January 28th, "Starvation in treatment," introduced by Dr. Edmund Spriggs; February 11th, "Eranche," Dr. Morland McCrea and Mr. Herbert Tiller; February 25th, "Acute Intestinal Obstruction," Professor A. H. Burgess and Mr. C. H. S. Franks; March 11th, "Chronic dyspepsias of children over the age of infancy," Dr. Reginald Miller and Dr. W. G. Wyllie; March 25th, "Medical indications for the induction of abortion and premature labour," Mr. Eardley Holland, Dr. B. T. Parsons-Smith, and Dr. Bernard Hart. These discussions will all begin at 8.30 p.m. The Lettsomian Lectures on "Dermatology in relation to other branches of medicine" will be given by Dr. H. W. Barber, at 9 p.m. on February 18th and 27th, and March 6th.

THE KING'S ILLNESS

The statement printed in our last issue at page 1106 brought the medical history of the King's illness up to 3 p.m. on Wednesday, December 12th, a few hours after pus had been located in the pleural cavity at the posterior base of the right lung, immediately above the diaphragm. The empyema was evacuated by rib resection under a general anaesthetic that evening, and the reports on Thursday indicated that His Majesty had come safely through the operation, and that drainage was proceeding. While the bulletins of Friday night and Saturday were not so reassuring about the patient's strength, those of Sunday and of Monday morning recorded some general progress and better sleep. After another temporary setback on Monday there was again some improvement, which has since been maintained.

The ups and downs of the past few days will not have surprised any medical reader of the bulletins, they were more than likely to happen after an operation for empyema in a patient of 63, already exhausted by a streptococcal blood infection. The public, too, have had many warnings that progress could only be slow and intermittent, and that anxiety must continue. The inevitable oscillations between hope and fear have none the less been very trying. Our King belongs to his people, and his illness has cast a shadow over every home.

We are able to print below a further authoritative statement, dated Wednesday, December 19th, 8 p.m., for the information of our readers, and through them for the steadying of public opinion. It is in keeping with the spirit of the age that this news, technical as it is, should have early and wide publicity.

"There are signs that the King's illness is producing in the public mind a sensitiveness, only too natural, caused by weeks of anxiety, and producing too easily alarm and therefore distress, both of which it is most desirable to avoid. Doctors, in their various spheres, can do much, by their knowledge, to maintain hope and confidence.

"The present condition of His Majesty can be best understood by recalling earlier stages of this severe illness. In the first phase, gradual in its onset, there were to be noted general infection with imperfect localization—little or no cough and only one small patch of pleuritic friction, blood culture positive (streptococcus), an irritative state of the nervous system which produced profound distress and sense of illness. Yet with these was a wish, born of quiet courage and the habit of duty, to make light of the illness and hold on to work, thus adding to the wear and tear of the fever. Towards the end of this first phase came an accentuation of pleuritic friction which extended to the diaphragm. The second phase was one of increasing toxæmia, with dusky appearance, dry cracked tongue, periods of delirium, exhaustion—in short, a clinical picture resembling that of a case of severe typhoid fever in the third and fourth weeks, but with the added anxiety of attacks of dyspnoea and cyanosis, due to strain on the heart. With the next phase came an abatement of fever and some evidence of localization. The blood culture was now negative, toxæmia was less, delirium subsiding. The localization in the right lung did not result at this stage in effusion, as shown by puncture and excellent radiographs. A few days later the temperature rose rather abruptly to a higher level, and on December 12th there was evidence at the extreme right base of an effusion which had commenced between the lung and the diaphragm. Drainage by means of rib resection was performed on the same day under general anaesthesia (gas-oxygen-ether). The predominant organism in the empyema has now been established to be identical with the streptococcus found in the blood.

"Though the infective process has become gradually localized, its severity, coupled with the lowered vitality resulting from the length of the illness, must make the progress of healing difficult and tedious. Local sloughing, however, is less pronounced to-day, and tissue reaction apparent. To stimulate vitality of tissues a brief general exposure to ultra-violet rays from a mercury lamp has been made each day since December 15th. The effect of these exposures is being checked by leucocyte counts and estimation of the bactericidal power of the patient's blood. There is reason to think that this employment of the ultra-violet rays has, in combination with the treatment mentioned in previous statements, been beneficial.

"It is hoped that the foregoing account will help towards an understanding of the future course of the illness. It will be apparent to medical men that not only the severity and length of the infection, but the exhaustion resulting therefrom, must make progress slow and difficult. At the same time, dangerous phases of the illness have been surmounted, and there are increasingly solid grounds for hoping that recovery will result from this long and anxious struggle."

The following medical men, in addition to those previously mentioned, have contributed to the care of His Majesty: Sir Hugh Rigby, Dr. F. E. Shipway, Dr. R. S. Woods, and Dr. F. D. Howitt. The names of the nurses in attendance are: E. Gordon, Catherine Black, Rosina Davies, and N. M. Purdie.

Ireland.

Encephalitis Lethargica made a Notifiable Disease

IN the course of a letter addressed by the Minister for Local Government and Public Health to the sanitary authorities in the Irish Free State attention is called to the *clinical and administrative aspects of encephalitis lethargica*, this disease, he states, was first observed in Austria in the course of the war, in the closing years of which it made its appearance in England and in Ireland, and has, in the subsequent period, assumed world-wide distribution. Encephalitis lethargica, or epidemic encephalitis, is characterized by certain manifestations originating in the central nervous system. As in other general infectious diseases, the symptoms vary considerably in character and severity. In the abortive, mild, or transient type the symptoms are restricted to soreness of the throat, nasopharyngeal catarrh, headache, vomiting or diarrhoea, accompanied by slight pyrexia. In the more serious forms of the disease many patients who survive the acute attack are later afflicted by motor disorders, characterized by rigidity and tremor, or by spasmodic movements, and certain forms of paralysis, and often by progressive lethargy and stupor. Various degrees of stupor have been noted. In the most severe form of attack the patient is described as lying in bed like a log, or resembling a waxen image in the lack of expression and of mobility. The prominent symptoms in a material proportion of recent cases have been lethargy and ocular paralysis, myoclonic movements, and sometimes twitching of the abdominal muscles. The disease attacks all ages, with a preference for the early and middle periods of life, and both sexes nearly equally. Encephalitis lethargica appears to belong to that group of maladies, including *cerebro-spinal meningitis* and *acute poliomyelitis*, in which the pathological agent is much more frequently present in the human organism than the clinical symptoms indicate. Although it is difficult to trace the infection from one person to another, it must be assumed that "missed cases" and "carriers" play a large part in the dissemination of these diseases. Since cases of encephalitis lethargica have been reported from various districts of An Saorstát, the Minister recommends that the disease should be generally added by sanitary authorities to the schedule of notifiable diseases through the procedure prescribed in Section 7 of the Infectious Disease (Notification) Act, 1889. He recalls the instructions contained in his circular letter of January 31st, 1923, wherein medical officers of health were enjoined to report encephalitis lethargica case by case. He adds that, in conjunction with encephalitis lethargica, it would be well if *cerebro-spinal meningitis* and *acute poliomyelitis* were also included in the group of notifiable diseases in any sanitary district where this has not already been done.

Sanitary Condition of Downpatrick

A report by Dr. Graham, medical inspector of the Ministry of Home Affairs in Northern Ireland, states that in Downpatrick there is no systematic inspection of the meat and milk supplies, and that the abattoir is not kept in a proper condition, the sanitary accommodation being used by neighbours, who create a filthy nuisance. He suggests that steps should at once be taken to prevent the public obtaining access to the place, and that the premises should be thoroughly cleansed and kept clean, but that the council should consider the erection of a new abattoir. The report also notes that while cases of infectious disease have occurred during the past twelve months no record is kept of them, and urges that a register should be supplied to the medical officer for the recording of all notifications of infectious disease received. The sanitary authority have not provided an efficient disinfecting apparatus for their district, nor adopted the provisions of the Infectious Disease Prevention Act, 1890. The water supply is not filtered in any way, and, owing to the small quantity in the service reservoir, the water is being used as it arrives from the collecting area without being subjected to the beneficial effects of storage. The inspector also calls attention to the fact that at the back of several small dwellings pigs are kept in most unsatisfactory conditions—a practice

which should cease, as the premises are unsuitable for the purpose and the creation of a nuisance is unavoidable. It is also pointed out that certain houses which were condemned many years ago are still inhabited, although they are situated over out-houses in which hens, etc., are kept, and there are obvious signs of rat infestation. The sanitary accommodation is also very defective. It is urged that these matters should receive early consideration by the council with a view to action being taken.

Paying Patients in County Hospitals

At a recent meeting of the Wexford County Health Board it was decided to adopt the draft regulations of the Department of Local Government and Public Health in regard to paying patients in the County Hospital, Wexford. The regulations provide that persons admitted to the private and semi-private wards shall pay to the Board a charge of 9s. per day in the first instance and 6s. in the second, together with appropriate additional charges for any special nursing or other expenses incurred in connexion with treatment. The medical officer and surgeon may agree with the person admitted as to the terms on which medical or surgical treatment shall be provided, and shall be entitled to demand payment of such agreed sums, but they shall, out of any sums thus received, pay to the Board any money due from such person to the Board, and which has not been paid or recovered by the nation of the hospital. Dr. M. O'Brien, surgeon to the hospital, was in attendance during the consideration of the question.

Scotland.

District Nursing in Scotland

At the annual meeting of the Scottish branch of the Queen's Institute of District Nursing, held on December 10th, it was announced that the Duchess of York had consented to become president of the Scottish branch in place of Princess Louise, Duchess of Argyll, who had resigned the office which she had held since 1890. The Countess of Mar and Kelch presided, and dealt with the work of the institute during the past forty years. It had risen from very small beginnings to an organization which now employed 710 Queen's nurses on the Scottish roll with, in addition, nurses in training homes in Edinburgh and Glasgow as well as other nurses in affiliated districts, supervised by the institute, making up a total of 850 nurses. Dr. J. Parlane Kinloch, chief medical officer of the Scottish Board of Health, remarked that the time was opportune to survey the whole position of the nursing service in relation to public health work. He said that there were, in the first place, training schools for nurses which had been recognized by the General Nursing Council under the Nurses' Registration Act of 1919. It was not satisfactory, however, that failure had attended the endeavour to link up the general hospitals with the fever hospitals, children's hospitals, and maternity and mental hospitals, so that the probationer nurse could receive within a period of four years a comprehensive training in nursing methods. He thought it would be a good plan for the council of the Queen's nurses to provide regional training schools for nurses, near the four universities of Scotland. The Central Government Department had prepared a syllabus of training which the whole-time health visitor must undergo, and within this course of instruction the trained health visitor might have a nurse's training also. He had come to the conclusion that the present arrangement whereby health visitors were required to devote their whole time to health visiting work from a health department, divorced from actual nursing work, was a bad one. The health visitor, in present circumstances, must lose her freshness of outlook because she was separated from fundamental nursing work. He suggested that the two services should be amalgamated and that the individual public health nurse, in charge of a smaller district than she managed at present, should undertake, in addition to nursing of the sick, the preventive work which the urban authorities required. He considered that every qualified nurse in future should

be an expert in preventive work, as she was at present in remedial work. Mr James Allan Cook gave details of the financial situation in Scotland. He said that two years ago then accounts showed a debit balance of £1,000, but at the end of the account now being closed there was a credit balance of £3,000. This satisfactory position was largely due to a sum of £6,000 received as the result of the Edinburgh payment.

University of Glasgow

At a meeting of the University Court of the University of Glasgow on December 13th a report was submitted by Dr Boyd on the work of the educational clinic, which had completed its second year. During the year the clinic had dealt with 100 boys and girls who had been brought on Saturday mornings by their teachers for examination because of some defect in learning or conduct. After two or three visits the staff had often been able to recommend a course of educational treatment, and in other cases, notably in regard to speech defects, the children returned at frequent intervals for supervision. The clinic, it was reported, had been of considerable benefit to the staff in gaining experience in this new field, and the work had also been highly appreciated by teachers. Cases of mental dullness had accounted for about half of the problems submitted, while speech defects were concerned in over one-fifth. At the same meeting it was intimated that Dr John Fergus had offered to establish a prize in connexion with the Muirhead chair of medicine, to take the form of books or instruments, as decided by the professor or Senatus.

University of Aberdeen

At a meeting of the University Court of the University of Aberdeen on December 13th it was announced that Dr Charles Reid, lecturer in experimental physiology in the University, had been appointed to the chair of physiology at Prince of Wales's Medical College, Patna University, India. Dr Reid, who is a graduate of Aberdeen University, succeeds at Patna University another Aberdeen graduate—namely, Professor E. W. H. Cruickshank, who has been appointed to the chair of physiology in Dalhousie University, Halifax. At the same meeting, it was intimated that the number of full-time students attending the University during the academic year 1927-28 had been 1,344, including 782 men and 552 women, together with 49 part-time students. Of the full-time students 711 lived in Aberdeen, or within a radius of thirty miles of it, 598 came from other parts of the British Isles, 25 from other parts of the British Empire, and 10 from foreign countries.

Control of Venereal Disease

At a public lecture given under the auspices of the Combe Trust in Edinburgh on December 5th, Dr David Lees took as his subject "The problem of infection," including that of venereal disease, and described the modes of entrance of bacteria into the body, and the barriers which nature sets up against them. He discussed the nature of the intensive campaign which had been waged against tuberculosis in this and other countries for the past quarter of a century, and expressed the opinion that a similar campaign was required to deal with the problem of venereal disease. He pointed out that syphilis and tuberculosis were in many ways alike—both were insidious in onset, both characterized by absence of pain, and in both the tissues of the body were slow in their defensive mechanism. He considered that of the two syphilis exerted the more harmful influence on the individual and on the national health. The facilities for free treatment had been utilized by many infected persons, but in spite of this initial success we were still left with the difficulty that we were unable to see it out and eradicate, as in the case of tuberculosis, the sources of disease. With progressive health legislation certain factors predisposing to the acquisition of the disease, such as overcrowding, bad housing and alcoholism, had been reduced. The provision of healthy amusements and recreation facilities in the form of sports had also been largely helpful, but he considered that the Church should play a much more active part in this campaign than it had taken up to now in the matter of inculcating chastity among the younger members

of the community. There was no field of medicine in which more striking results could be promised and attained than in the eradication of venereal diseases in children by treatment of the parents. It would appear that the stamping out of venereal disease was possible, and the failure to make greater progress than was taking place was due to many causes. A higher moral standard in the community and a more extensive knowledge of the dangers were important, but there would still exist in every community irresponsible persons who cared little for their own health and less for that of others, and the problem of how to deal with this minority was a vexed one. There was a large body of opinion, chiefly among those who were in close contact with the work, which believed that health authorities should be empowered to deal with people of this type as dangers to themselves and to the community. As education of the public advanced he believed that a demand would come from the educated public for the control of those irresponsible persons who spread venereal disease.

England and Wales.

King Edward's Hospital Fund

The annual distribution meeting of King Edward's Hospital Fund for London was held on December 14th, with the Lord Chancellor, Lord Hailsham, in the chair. Lord Hailsham read a letter from the president, the Prince of Wales, in which His Royal Highness expressed regret at his inability to be present, and took occasion to congratulate the Fund on its achievements during the year. The meeting adopted a resolution voicing sympathy with the King in his illness and the wishes of the members for his speedy and complete recovery.

Lord Hailsham, before proceeding with the principal business of the meeting, referred to the recently announced gift of £50,000 from Sir Otto Beit for the purchase of radium, which, he said, opened a new field for the activities of the Fund as a central body for the hospitals. The distribution this year, he continued, constituted in itself a great landmark in the history of the Fund, for it was the first time that the ordinary annual distribution had reached the total of a quarter of a million. When King Edward, as Prince of Wales, founded the Fund in 1897, he aimed at £100,000 a year. The distribution was now two and a half times this amount, yet, with the increase in the number of beds, the development of expensive treatment, and the changes in the value of money, the demands on the Fund had grown in even greater proportion. The year's success had been due largely to some special donations, notably two of £10,000 each from anonymous donors. The Fund had also received an exceptional amount in legacies, but it had depended largely for its success on the steady support of the smaller contributions, including the amounts collected by the League of Mercy. Lord Hailsham then referred to the report of the Pay Beds Committee of the Fund, published in July, of which a summary appeared in the *Journal* of July 21st (p. 120). He had left to the last, he said, the biggest of all the problems with which the King's Fund and the voluntary hospitals were faced at the present moment. The transfer to the county councils of the Poor Law infirmaries would produce great changes, and, they hoped, great improvements. It would be necessary to work out a scheme by which the voluntary hospitals should continue to make their special contribution to the hospital service which depended on the fact that their management was voluntary and that their finance was voluntary. The voluntary hospitals were engaged in considering the principle of co-ordination between themselves and the new county hospital service so as to preserve these essential features. In this discussion the King's Fund must necessarily take an active part and for this reason they had appointed a special committee. They hoped thus to provide a means of focusing the opinion of practical hospital people and bringing it effectively to bear, both during the discussions on the Local Government Bill and during the subsequent preparation of schemes by the

county councils and other local authorities in the King's Fund area.

Lord Revelstoke, honorary treasurer said that it had been the considered practice of the Fund not to augment the amount of the annual distribution without having a reasonable prospect of being able to maintain it in the future at not less than the increased figure. When, at the beginning of last month, the council met to determine the amount of the ordinary distribution the estimates pointed to the conclusion that this important step would be justified, and the total distribution was therefore increased from £247,000 to £250,000. Lord Marshall stated that the League of Mercy proposed again to allocate £17,000 to the King's Fund and that its grants to extra-metropolitan hospitals amounted to £8,210.

Sir Cooper Perry chairman of the Distribution Committee, presented the report of that body in which it was stated that the number of hospitals applying for grants was 141 the same as in 1927. The report mentioned that the Federated Superannuation Scheme for Nurses and Hospitals Officers came into operation at the beginning of the year, and that by the beginning of October eighty-nine hospitals had joined the scheme. A schedule containing a list of awards to hospitals (including recovery and convalescent branches) was presented by Colonel Wernher, honorary secretary. Among the larger grants were

Charing Cross Hospital £4,750 Guy's Hospital £11,500 King's College Hospital £7,000 London Hospital £15,150 Metropolitan Hospital £4,750 Middlesex Hospital £8,750 Miller General Hospital £4,850 Prince of Wales's General Hospital £5,100 Queen Mary's Hospital £4,750 Queen's Hospital for Children £4,800 Royal Free Hospital £7,500 Royal National Orthopaedic Hospital £4,750 Royal Northern Hospital £9,850 St Bartholomew's Hospital £6,000 St George's Hospital £8,200 St Mary's Hospital £6,000 St Thomas's Hospital £10,000 University College Hospital £8,000 West London Hospital, £5,500, and Westminster Hospital £4,450.

Medical and Dental Treatment of London School Children

The arrangements for the medical and dental treatment of children attending public elementary schools and scholars and pupils in secondary schools for the year April, 1929, to March, 1930, were considered by the London County Council on November 27th. The arrangements authorize slight increases in the number of cases of eye defects, ear, nose, and throat conditions, minor ailments, and dental disorder for which provision may be made. The total number of cases for which provision is authorized for 1929-30 is 273,000, of which 139,000 are dental cases, and the estimated cost of the arrangements exclusive of standing charges is £105,500, of which dental cases account for £47,000. These figures represent an increase of 8,000 cases above those authorized for the current year, and an increased expenditure of £3,784. It is stated that the in-patient method of dealing with throat operation cases (tonsils and adenoids), whereby the children are kept at the centre for two nights instead of being immediately sent home, has been very successful. All the centres have been fully occupied, and there has been congestion at last Friday centres. Provision is made to enable further in-patient treatment to be given should the opportunity arise for obtaining additional accommodation. Five or six new minor ailment centres are to be opened during the coming year as well as one additional centre for the treatment of stammering children. With regard to rheumatism the Council in February last decided to establish five supervisory centres to which children suspected to be rheumatic or requiring observation for rheumatism might be brought periodically for advice. The centres in question are the Hospital for Sick Children (Great Ormond Street, London), the Queen's hospitals and the Downham and Elizabeth Bullock school treatment centres. At the three hospitals the children are dealt with at special weekly sessions in the out-patient department and the medical officer in charge of the department undertakes the examination and treatment. At the two school centres one half day a week is set apart for rheumatism cases, and one of the Council's medical officers attends to examine the children and advise as to treatment. The cases for examination and treatment are selected by the school doctors. It is stated that during the two weeks that the scheme

has been in operation very satisfactory results have been obtained. The parents greatly appreciate the facilities afforded, and no difficulty is experienced in securing the attendance of the children at the centres.

Fees of Medical Advisers in Tramway Claims

The fees paid by the London County Council to the medical men—not more than three in number—who are retained as advisers in connexion with tramway accident claims have hitherto been as follows: a retaining fee of £42 a year, half a guinea for each examination, and 2 guineas for each attendance at court to give evidence, with special fees if attendance is required outside the county of London. The fees for examination and court attendance are subject, until March next, to an increase of 25 per cent. The two medical advisers are both resigning, and in making the new appointments it is proposed to revise the fees to make them comparable with the fees paid by insurance and other companies. It is proposed by the Highways Committee, with the concurrence of the Finance Committee, that the retaining fee be abolished, the fees for attendance at court remain as at present, and the fees for examinations be varied in accordance with the distance of the case from the medical adviser's residence: up to five miles, £1 1s, over five and up to seven miles, £1 11s 6d, over seven and up to nine miles, £2 2s, over nine and up to thirteen and a half miles, £3 3s, over thirteen and a half and up to eighteen miles, £4 4s, and over eighteen miles, special fees to be determined by the solicitor. These fees will not be subject to the 25 per cent increase.

Correspondence.

PROBLEMS IN GASTRIC SURGERY

Sir,—I feel sure that your readers were more than ordinarily interested in Sir Berkeley Moynihan's article on problems in gastric surgery (December 8th, p. 1021), in which he states with great clearness his position in the gastro-enterostomy or gastrectomy controversy. As a judicial summation of the present situation his contribution is valuable, but one cannot help feeling that there is a certain amount of bias shown towards the operation so closely associated with his name.

There is, perhaps, a danger that the weight of his opinion and experience, welcome as it is, may tend to overbalance the considered conclusions of others whose collected experience must be much greater again.

In stating that I "fail to recognize the necessity for direct treatment of a duodenal ulcer in addition to gastro-enterostomy," he inadvertently conveys the impression that I am without experience of this method, which is far from the truth. For several years I have, when treating duodenal ulcer by gastro-enterostomy, either excised the ulcer completely or dealt with it by Balfour's cauterization method. The reason I cannot agree that this point is the key to success is not, therefore, lack of experience with the method, but the fact that I have seen cases of haemorrhage and perforation follow its performance, and that endoscopy of the duodenum so frequently reveals multiple ulceration that nothing short of duodenectomy would suffice to deal directly with the ulcerative condition. Sir Berkeley Moynihan himself owns that ulcers on the posterior wall may be found more often than his operation figures indicate. I am convinced that this is so, the surgeon is only too apt to forget that the duodenum has a relatively inaccessible posterior wall. If I could believe that the ulcer was the essential part of the disease and not a mere incident in a much more widespread process, I could the more readily agree with the importance of removal. The partial duodenal stenosis which widespread removal may produce is perhaps the explanation of improved results following removal, many surgeons habitually perform pyloric exclusion for the same reason.

The second point to which I should like to refer—namely the radiographic evidences of cure—is already raised by Dr. Fildes in this week's issue (p. 1110). In justice to Sir Berkeley Moynihan, it should, however, be pointed out that his statement (with which most will agree) was that

"he had never seen an ulcer of the site depicted here in less than four months," tacitly implying that the real ulcer in the case quoted could not have been of the size radiographically demonstrated, a circumstance explained, as Dr Fiddes points out, by Dr Burchley's article upon the interpretation of radiographic appearances. This article was a touch one, and presents succinctly conclusions to which many interested in gastric diagnosis had been forced.

I notice, however, that Dr Barclay attributes the heaping up of the mucous membrane to local spasm of the unsmoothed mucosae, whereas in my own experience it is due mainly to the inflammatory oedema of the submucosa surrounding the ulcer, which is always present in the active phase of ulceration when the patient is most commonly examined. This is well seen either when an ulcer is exposed by gastrotomy or by the endoscope, but for obvious reasons is not so easily demonstrated on the removed specimen *in post mortem*. It is indeed important to realize that the periods when the patient gets most pain are those in which there is a cellulitis of the surrounding submucosa, the chronic ulcer in the quiescent stage producing, in the absence of complications such as stenosis, comparatively slight discomfort—I am, etc.,

London W Dec 15th

NORMAN C LIVER

ARTIFICIAL RESPIRATION FOR WHITE ASPHYXIA OF THE NEWBORN

SIR,—I fully concur with every word of Mr Aleck Bourne's letter in your issue of to-day (p 1109). The "white baby" is not asphyxiated. The term "white asphyxia" should be eliminated from all textbooks and the word "shock" substituted for it. I should like to add one suggestion as to treatment. The flaccid condition of the child, especially of the abdominal wall, readily allows of direct cardiac massage by placing the thumb of the left hand over the precordia while the fingers of the hand are tucked in under the diaphragm. By gently squeezing the thumb and the fingers together the heart is stimulated to contract quite easily. In my experience cardiac massage is perhaps the most valuable method of treating the "white baby"—I am, etc.,

London W 1, Dec. 15th

HENRY SIMON

SIR,—Mr Aleck Bourne's important letter on this subject is of much interest to all who practise midwifery. With his conclusion, "that in the aggregate more harm is done by attempting artificial respiration than by its complete abandonment," I am in complete sympathy. Nevertheless, after reading the letter, an impression is left that mechanical interference is of no avail and should therefore be avoided. In view of certain experiences I venture to suggest that this is not always the case.

Occasionally a child's first inspiration may be hindered by some obstruction, and, if the child is feeble and shocked, there may be insufficient strength to overcome this obstruction. Professor B P Watson popularized in Edinburgh the old method of aspiration of mucus from the throat by direct suction through a special glass pipette. The amount of thick tenacious mucus which can be removed from the pharynx by this means is sometimes astonishing. Such mucus must, at times, be responsible for partly or wholly blocking the air way.

With regard to artificial respiration, this is probably unnecessary in the first five or ten minutes. Sylvester's and Byrd's methods, as Mr Bourne shows, are ineffective and not devoid of danger, but the condemnation of direct mouth to mouth insufflation is perhaps unjust. One has reason to believe that on more than one occasion one has saved a child by this procedure. The belief in the value of this method has been strengthened by the following case.

I witnessed a difficult forceps delivery. The child was born pale, flaccid and apnoeic. The usual restorative methods were tried without avail and after ten minutes the heart beat became slow and feeble. At this point one volunteered to do direct insufflation through a layer of gauze. After ten or twelve breaths the child's heart began to beat strongly and rapidly, the skin changed from white to a rosy tint and some tones returned to the limb muscles. The child, however, did not breathe spontaneously and after a minute or two lapsed into its previous state. The procedure was

repeated with the same encouraging results, but these again disappeared on stopping treatment. The insufflation was continued at intervals for fifty minutes from the time of delivery and the repeated improvements were apparent to all present. Substituting other more elegant methods of artificial respiration was of no avail. After fifty-five minutes the heart beat finally ceased. At post mortem examination a deep tear of the tentorium cerebelli was found similar to those described in so much detail by Holland. There was a considerable haemorrhage around the tear and this presumably accounted for the paralysis of the respiratory centre. The stomach was only moderately distended by air owing to the pressure kept up on it at the time of the treatment.

This case well proves the value of direct insufflation in neonatal asphyxia.

While, therefore, agreeing that in a pallid child the treatment of shock is of first importance, and too hasty and too vigorous means of artificial respiration are to be avoided, I feel that there are cases where the child's life may be lost by an excess of masterly inactivity in the treatment of asphyxia neonatorum—I am, etc.,

J CHURCHILL MOIR, M B, F R C S Ed

Redhill, Dec 15th

PULPITAL MORBIDITY

SIR,—In your issue of December 15th (p 1082) there is a very interesting paper by Drs Armstrong and Shaw, but in it there is a very grave error. The statement is made that according to the B M A standard, if the temperature reaches 100.4° F on two occasions between the second and tenth days of the lying-in period, the patient is morbid.

In making up our statistics we take as the B M A standard that if the temperature should reach 100° F on any two occasions between the second and eighth days, the patient is regarded as morbid. All deaths, with or without fever, are included.

It is most important that there should be absolute accuracy when a uniform standard is taken; otherwise it will not be possible to compare the health of one institution with that of another—I am, etc.,

BETHEL SOLOMONS,
Master Rotunda Hospital

DENTAL CARIES AND VITAMIN D

SIR,—I have read with much interest the account, published in the *Journal* of December 15th (p 1079), of the investigations carried out by Mrs Mellanby and Mr C Lee Pattison on the influence of vitamin D, administered in the form of radiocitol, in promoting calcification of the teeth. Whatever that effect may be, the work of these investigators must not blind us to the incontrovertible truth that dental decay is initiated by the corrosive action on the enamel of an acid formed by the fermentation of saccharide (carbohydrate) food, and that tooth enamel can offer no more resistance to that acid than a block of marble. It is simply a question of the affinity of a certain acid for calcium. The initiation of dental decay can therefore have nothing to do with the less or greater resistance of the tooth to the action of acid. That which determines the onset of caries is the prolonged contact with the enamel of fermentable saccharide food. Accordingly, caries begins in those situations where such prolonged contact is apt to occur—namely, in the pits and crevices of the teeth (notably on the grinding surfaces of the molars) on the adjacent surfaces of the teeth, and at the necks of the teeth. Caries never begins, no matter what the nature of the food past or present, on the smooth surfaces of the enamel which are kept clean by the adequate friction of tongue, lips, and cheeks. Let us hold fast by these essential truths, and let us, as medical men, lose no opportunity of bringing them home to mothers and school teachers. Only in this way is it possible to cope with the calamitous condition of the teeth of the people of this country. All dental decay is preventable, by simple, common sense means—I am, etc.,

London W Dec 15th

HARRY CAMPBELL

SIR,—Those who are well acquainted with the theory that the prevalence of dental caries is due to the undue lodgement of easily fermentable carbohydrates in the retention areas of the teeth will find additional evidence of its

truth in the experiments recorded by Miss May Mollinby and Mr C. Lec Pattison in your issue of December 15th.

The results given with regard to different groups of children are admittedly not strictly comparable, not particularly, however, because of age, but because the diet of those children in the group getting radiostol differs materially from the diets which appear to be regarded as controls. We can analyse certain differences between the diets in the radiostol group and in the group referred to in Table I, as the dietary in this latter was recorded in the *British Medical Journal*, August 30th, 1924 (p. 355). It will be noted that in the radiostol, but not in the other group, one ounce of bacon and half an ounce of cooking fat were present in the average daily diet. Both of these items are recognized generally by the dental profession to be antagonistic to the onset and progress of caries. Again, the amount of sugar was limited to one ounce in the radiostol group, whereas in the other group it varied from one and a half to three ounces daily. As sugar is recognized to be more conducive to dental caries than any other carbohydrate it is easy to see how the results recorded came about.

I need not discuss the rest of the paper, as to a great extent it only tends to divert attention from these essential facts, and to bias judgement with regard to the effect of the so-called vitamin D, for, so far as the evidence goes, there seems to be no reason for assuming that radiostol had anything whatever to do with the results recorded in the group of children to which this drug was administered—I am, etc.,

London W. Dec 17th.

J. SIM WALLACE

ABDOMINAL FRICTION IN PERITONITIS

SIR,—Dr. Walter Broadbent, in his interesting note in the *Journal* of December 8th (p. 1103) does well to refer to abdominal friction in early peritonitis—a subject which, as he says, does not seem to be mentioned in the textbooks. I have noticed these friction sounds in a case of acute cholecystitis and in several early cases of appendicitis—first attacks. In my cases of appendicitis the friction sounds were detected by both palpation and auscultation, and in each case the signs were evinced less than eight hours after the onset of the attack. The sounds disappear after the accumulation of fluid in any quantity in the peritoneum, and, in chronic cases becoming acute, adhesions probably prevent much peritoneal gliding (the cause of the friction) taking place. Hence the sounds are heard in first attacks of appendicitis as a rule. I have elsewhere¹ suggested the term "peritoneal crepitus" for these phenomena.

I have read an article by Dr. J. A. Ryle in which he refers to these friction sounds in acute cholecystitis—I forgot for the moment where. I have never seen them referred to among the earliest unequivocal signs of acute appendicitis—observed before the occurrence of a rise in temperature—I am, etc.,

ANDROSE W. OWEN

THE MEDICAL PROFESSION, THE VOLUNTARY HOSPITALS, AND THE DE-RATING BILL

SIR,—Some very pregnant words which occur in the Minister of Health's speech in committee upon the De-rating Bill (*Hansard*, December 13th, column 2460) I think deserve the attention of the medical profession. I quote the words:

'Let no hon. member run away with the impression that the Government desire that those who have been treated under the Poor Law in the past, in the case of medical relief, should continue to be treated in that way. Our policy, the policy of the Ministry of Health—at any rate as it is conducted at present—is exactly what my hon. and gallant friend (the member for Derby [Sir R. Luce]) desires that it should be. We desire that people who are sick shall be treated according to the nature of their sickness and not according to whether they are destitute or otherwise.'

These ideals seem to approach dangerously near to the grandiose conceptions of the Labour party, whose schemes for social services, if they matured, would, as Sir Herbert Samuel has recently pointed out, add an annual expendi-

ture of something like 226 millions sterling to the present cost of social services, which are already responsible for considerably more than a third of the total expenditure of this country upon all its administrative and imperial activities. It envisages a condition of things which is humorously sketched by Dr. Walter Carr in his very interesting address to the Medical Society a time when there will be no private practice at all, but the State medical departments will have supreme authority over the treatment, the hygienic regulations, and education of every member of the community.

Evidence is not lacking that the medical profession is at last becoming somewhat disturbed at this prospect. The King Edward's Fund, that good friend of the voluntary hospitals, has taken the wise precaution of setting up a special committee to watch the development of the De-rating Bill as it concerns the voluntary hospitals, but it seems to me that not only the voluntary hospitals but every medical man in this country is deeply concerned in this question. The manner in which the De-rating Bill has come before Parliament makes opposition extremely difficult to the proposals which more particularly affect the medical profession, but that profession is not without its influence if it can be induced to exert it, and it seems to me that the very large cat which the Minister let out of the Ministerial bag in his speech on Wednesday last deserves very careful watching.

I have received an invitation, which I have accepted with much pleasure, to deliver the Harveian Oration before the Harveian Society next March on the medical profession, the voluntary hospitals, and the De-rating Bill, when I hope to have an opportunity of expanding my views upon these subjects. But as decisions will probably have been taken upon some of these questions before that date I venture to invite the attention of the profession to the subject now—I am, etc.,

London, W. Dec 15th

E. GRAHAM LITTLE

PAINFUL SHOULDER

SIR,—From your interesting and comprehensive editorial notice of the discussion on this subject at the Royal Society of Medicine (December 15th, p. 1103) it is clear that not one speaker mentioned the pathological condition which is responsible for a very large number of cases—namely, traumatic synovitis of the shoulder-joint. I cannot understand this omission, for in my hospital practice, which cannot differ very much from that of others, I and those who work with me see and treat cases of this trouble every week.

There is a history of a sudden strain or wrench, or of a fall on the shoulder, or of a dislocation which has been reduced in the ordinary manner. The symptoms are:

1. *Stiffness or limitation of movement.* The patient finds he cannot raise his hand above his shoulder, cannot brush his hair or take his hat off, has great difficulty in putting his arm into his sleeve, and still greater difficulty in taking it out, cannot place his hand behind his back to do up his brace button.

2. *Constant dull aching pain,* made worse by movement, and very much worse if he attempts to carry out any of the movements which are limited. This pain is very troublesome at night and interferes with sleep, especially if he lies on the damaged side. He says he cannot lie on that side, and that though he goes off to sleep all right he very soon gets wakened up by the pain, he manages to get into a comfortable position and dozes off only to wake again because of the pain, and so it goes on all night.

3. *Presence of two tender spots on palpation.* One is on the outer side of the arm between the deltoid and biceps the other is at the outer end of the infraclavicular fossa. These spots may be so tender that the patient starts involuntarily when they are pressed upon.

The shoulder in this condition is never swollen up with fluid as is the knee under similar circumstances, it seems that the excess of synovial fluid drains away down the tendon of the biceps. Treatment does not consist in massage and movements, ionization, diathermy, or radiant heat, but is solely by rest beneath the clothes. The wrist is tied to the neck in a knotted sling, and left there day and night until the tender spots are no longer tender and until the patient can sleep all night without the pain waking him once. This usually takes two or three weeks.

¹ *Lancet* 1925 vol. i p. 518.

This condition was described admirably by Thomas in his *Contributions to Surgery and Medicine*, Part III, 1887 (pp 29-51)—I am, etc.,

London W. Dec 13th

PAUL BERNARD ROTH,
Orthopaedic Surgeon, Wilkes Hospital

IODIZED OIL IN DIAGNOSIS AND TREATMENT

SIR,—Those workers in this country who employ iodized oil for diagnosis and treatment will be interested to learn that a British preparation, an improved iodinol, is now on the market containing 40 per cent by weight of iodine. The new iodinol has been made by Dr. Muntandale. It is a clear yellow liquid, containing no free iodine, and it can be sterilized by heating in a water bath without decomposition. I have used it for injecting into the lung. The resulting pictures are excellent, and there is no irritation of the mucous membrane—I am, etc.,

T. C. CHAMBERLAIN, M.D., F.R.C.P.

London N.W.1 Dec. 5th

THE TEAR-REFLEX TEST FOR ASTHMA OF NASAL ORIGIN

SIR,—Mr M. Mortimer Whitty in your issue of December 1st (p 985) contributed a memorandum on the tear-reflex test for asthma of nasal origin. This, I feel sure, will be of great help to the practitioner in the differential diagnosis of the various types of asthma. In nasal asthma as is well known, the treatment of gross pathological lesions—for example, mucous polypi, paranasal sinusitis, etc.—is of great value in the prophylaxis of this malady. In the absence of these conditions it has been my custom to touch gently with a silver probe the mucous membrane of the conchae and the tubercle of the septum to discover centres the palpation of which may induce sneezing or coughing, in other words, to elicit the "cough spots" described by McBride some years ago. True linear cartilization of these areas in the majority of cases greatly ameliorates the condition of the patient, increasing the intervals between the asthmatic spasms. One can imagine the tear reflex described by Mr Mortimer Whitty to be a test more delicate and more easily elicited far whereas the production of tears by probing the nasal mucous membrane is confined to the sphenoidal division of the fifth nerve the induction of coughing is obtained by a more circuitous route—namely the sphenoidal division of the fifth sympathetic and the vagus or possibly by the close proximity of the nuclei of the fifth nerve and the nucleus ambiguus in the floor of the fourth ventricle—I am, etc.,

BOOKS AS POMITES

SIR,—The procedure in Hampstead for many years has been that the public health authority notifies the public library authority of any cases of notifiable disease received and should any member of the household concerned be in possession of a public library book it is sent for and either destroyed or disinfected. Unfortunately there are many libraries now where for a small subscription books can be borrowed and where such safeguards cannot so easily be applied, and these may be a real source of danger. Perhaps our sanitary inspectors should inquire whether such books have been in contact with notified infectious cases when they visit the house concerned and notify the appropriate lending library—I am, etc.,

Hampstead N.W., Dec. 8th

CECIL W. CUNNINGTON

AVULSION OF THE SCALP

SIR,—Moved thereto partly by Mr Gillies' despatching irony and partly because I had the privilege of visiting Sidcup in 1918, I feel compelled to offer him some explanation by way of apology for my sins of omission. Mr Gillies's work on plastic surgery is so well known and so closely associated with the technique of tube grafting that mention of the latter almost automatically recalls the former. That I did not specifically refer to it is solely

because on perusal of his book I could find no detailed account of a precisely similar case. Ogilvie's *Recent Advances in Surgery* in which Mr Gillies's case is illustrated, was not published till nearly two years after the operation on my case had been completed, and I became aware of it too late for inclusion in my references. I make no claim to originality, and am glad to have this opportunity of acknowledging my indebtedness to Mr Gillies—I am, etc.,

Ipwich Dec 11th

A. GREY BANKS

ULTRA-VIOLET RAY THERAPY

SIR,—May I endorse the views expressed by Dr I. C. Mudie in your issue of December 1st (p 1011) regarding the effect of ultra-violet radiation in highly nervous cases? It seems to me that successful treatment of such conditions depends entirely on the recognition by the operator that the patient must be treated "judiciously." I have found that radiation of the whole body as too stimulating—symptoms are aggravated and my rule now is to radiate a comparatively small area—for example, back or chest—at a sitting, and to aim at the production of a mild erythema only. My nerve patients come three weeks and in the vast majority of cases improvement is very soon admitted and apparent. Unlike Dr Mudie I do not combine radiation with any internal medication but rely on the good work of the mercury vapour lamp—I am, etc.,

Edgboro Dec 3rd

ANDREW SMITH HANNA

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THREE days in the House of Commons this week were allotted to the committee stage of the Local Government Bill and arrangements were made for a debate on distress in the coal-fields before the adjournment of the House for Christmas, which was proposed to be from December 20th or 21st till January 22nd.

Local Government Bill

The committee stage of the Local Government Bill began in the House of Commons on December 13th.

Mr A. GREENWOOD moved an amendment providing that the council of a borough or urban district with a population of not less than 20,000 might become a Poor Law authority.

Dr FREDERICK REMOND moved the House that the Royal Commission on the Local Law had strongly advised the county area as the unit of administration to deal not simply with the Poor Law but with the causes of poverty, one of the chief of which was ill health. The question of health arose not only in institutions but before people entered them. So long as local experience was used wherever possible as the bill proposed it was necessary to have co-ordination under the county authority. He opposed the amendment.

The amendment was defeated by 218 to 151.

On Clause 3 (provisions as to alternative powers of giving assistance) Sir RICHARD LUCE moved an amendment to remove the option which the bill gave to local authorities in the working of certain parts of the health services and to insure that as far as possible in future, those services which could be administered under existing Acts should be so administered and not by way of poor relief. He said that this amendment and two others on the paper dealing with the same point would not completely transfer the medical services from the public assistance committees unless further action was taken under Clause 5 where power was given to the county councils to direct that parts of their duties should be transferred to committees other than the assistance committees. Sir Richard suggested that the bill did not carry out the Minister's proposal to co-ordinate the medical services in each area. If a large portion of the duties was left to the new assistance committee—which really only replaced the old guardians—medical services would not be divorced from other public assistance although such a divorce was necessary for the effective co-ordination of medical services. The assistance committee was not really a suitable committee to undertake the duties which the bill would impose upon it. Its first duty would always be the provision of monetary assistance to the poor. The administration of the medical service had in the past been one of the great failures of the guardians. There had been notable exceptions but on the whole he could not say that the medical services for the poor provided by the guardians had been as good as those administered through voluntary hospitals. It would be advantageous to transfer medical matters to committees which were already devoting their time to these subjects. A new assistance committee would have to be trained in the duty of medical relief and Parliament would be duplicating work in which other committees were already trained. They now had a

medical officer of health who was the adviser of the health committee and of other committees which dealt with health matters. He would be compelled to divide his attention and to be one of the officers in direct touch with the new assistance committee. Everyone admitted that something should be done to remove the stigma of pauperism from those to whom it attached merely from the fact that they were sick, or suffering from some disability. It would be difficult to do that unless there was a divorce between the medical cases and the cases of paupers who were paupers only. Furthermore until these two services could be divorced it would be impossible to carry out the new organization that was required and the co-ordination between the voluntary system and the other medical systems of the country. That end required one definite authority in each area by whom co-ordination could be organized. He realized that there were certain difficulties in his proposals. Poor Law hospitals at present were often in the same building as the rest of the Poor Law institutions but the schemes which had to be prepared under the bill should so far as possible divert the various hospitals and institutions to different duties. That could not be done so long as each hospital or each institution was doing all sorts of work as in Poor Law hospitals at present.

In his speech on the second reading of the bill Sir Richard Luce continued the Minister of Health had said he favoured the eventual divorce of medical service from the rest of the Poor Law but had given two objections. The first and most important was that many local authorities had not the machinery to carry out the various health services as they ought to be carried out under the relevant Acts. One of the amendments put down by Sir Richard and his friends would get over that difficulty by allowing the Minister to give a time limit to authorities which were not yet ready. Within that limit they could still work their existing system of pauper relief. Without a time limit a refractory or reactionary area might go on indefinitely under the present system. Assistance committees once they had started on medical work would be very unwilling to give it up and Parliament would have over again all the trouble they had now in getting rid of the guardians. The second objection which the Minister had raised was that he was loath to interfere with local authorities in the management of their own affairs and would prefer to give them the option to work in the way they thought best. But the best method of work was by the divorce of the medical service from the other services, and if there was a danger of then not working according to the best method it was not right to give local authorities this option. Parliament was engaged in a very important reform of Poor Law, and it would be a great pity to halt half way. Sir Richard added that he realized that the vast majority of local authorities would adopt the better method.

Mr. SIMON WEBB heartily supported the amendment and said that Sir Richard Luce had put the points for it extremely well. He observed that the chief reason why public medical assistance was given was that the patient should go for treatment at the earliest possible moment. Large sums were given out of the rates to deal for instance with cancer. In some places that was done under the Public Health Acts and in other places under the Poor Law. Unless unfortunate people were induced to come at the earliest possible moment the mortality would be intensified by delay to give treatment as poor relief was not the way to induce people to come as quickly as possible. Pauperism meant that the pauper was subjected to a positive legal disability. If a patient went into a voluntary hospital and received treatment as a charity he had the right of action against the hospital authorities and the servants of the hospital if there was gross negligence. In a case tried the other day in connexion with a maternity home the right of action was not denied though the action was not successful. The pauper was deprived of this right of action and was left undefended against negligence by the superintendent or nurse—he did not like to say by doctors although there had been such cases. Mr. CHAMBERLAIN said the difference in legal liabilities of guardians and voluntary hospitals was not so great as Mr. Webb had represented. Recently when a metropolitan board of guardians was sued for damages to a boy whose arm had been injured they settled the case with the judge's approval by paying £1,000. On the other hand it had been held that a public health authority was not responsible where a doctor improperly discharged a patient from a fever hospital. The governors of a voluntary hospital were not responsible where negligence had been alleged against a nurse acting under the orders of a doctor.

On the actual amendment Mr. CHAMBERLAIN thought there was no difference between those who supported the amendment and the Government. The Government did not desire that in the case of medical relief those who had been treated under the Poor Law in the past should be so treated. It desired that people who were sick should be treated according to the nature of their sickness and not according to whether they were destitute or otherwise. That policy could not be carried out completely until the power given under Clause 4 had actually been used by local authorities. The Minister desired that these should take advantage of it at the earliest possible moment. When the bill had reached the statute-book a circular letter would be sent out from the Ministry of Health to local authorities calling attention to particular points in the Act and indicating the view of the Ministry on the intention of the Act and the way in which that intention should be carried out. The Government did not make this clause mandatory because things as they were at this moment would not allow this arrangement to be carried out. Some time must be given local authorities to make necessary adjustments. To get the full advantage and effect of the reform which they proposed they must allow the county councils to make a survey not only of the needs but of the existing

institutions and to consider how these institutions could best be adapted. That might mean vast structural alterations and time must be allowed for the councils to consider what was wanted and to make the requisite arrangements. It would be necessary, if the clause were mandatory, to give the Minister power to suspend it as Sir Richard Luce had recognized. Was it essential to do so when they well knew that it must be suspended everywhere? If Sir Richard Luce meant by his amendment that the policy of the Government should be made more clear Mr. Chamberlain would further consider that point before the report stage, and if words could be found to make clearer the intention of the Government he would then have them inserted to indicate that local authorities should pursue the plan advocated by Sir Richard Luce as and when facilities were open for them to do so.

Sir RICHARD LUCE said that in view of Mr. Chamberlain's sympathy and his promise to reconsider the point he wished to withdraw his amendment. The amendment was by leave withdrawn.

On December 17th the House again went into committee on the bill. Clause 5 enacts that an administrative scheme for the constitution of a Public Assistance Committee should be made by the county councils and county boroughs. Mr. LANSBURY moved an amendment to delete the reference to the Public Assistance Committee and to substitute that the scheme should provide for the delegation of the transferred functions to appropriate committees of the council. Mr. CHAMBERLAIN in opposing the amendment said that exactly the same ground had been covered on Clause 4. His answer to the amendment was exactly the same. It was simply that it would be physically impossible to hand over to the appropriate committees all the varied functions which were to be transferred. Many local authorities would be in the position of having no public hospital and only a Poor Law institution. To make a proper scheme the new authority would have to sit down and consider all the institutions. They could not make that survey and carry out the structural alterations necessary in a day.

Mr. WEBB said that the amendment which the Minister of Health would move later on would allow the London County Council to transfer to any of its committees any functions whether they were performed under the Poor Law or under the Education or Public Health Acts. In other words, under the terms of that amendment the London County Council would be able to transfer to what was called the Public Health Committee not only the functions which it exercised under the Public Health Acts and other similar Acts but also functions in regard to the sick and infirm which could be carried out by the guardians and the education committees. The same freedom should be given to other large authorities in the country.

The amendment was rejected. The guillotine motion soon afterwards came into operation and under it the discussion on Clauses 5 to 8 automatically came to an end. As a result Dr. Fremantle's amendment to Clause 5 was not debated. Another amendment, in the name of Sir Richard Luce and Dr. Fremantle providing that all matters relating to the exercise of the transferred functions, except the raising of a rate or borrowing money should stand referred to the Public Assistance Committee or such other committee of the council as the council should so determine, was passed over.

On Clause 6, which provides for the appointment of guardians committees and subcommittees a further amendment by Dr. Fremantle was cut out by the guillotine. Clause 7 provides that as soon as an administrative scheme has been submitted to the Minister of Health the council submitting the scheme shall publish a notice of the fact in the local newspaper. An amendment to this clause by Dr. Vernon Davies was also guillotined.

On Clause 9 which deals with disqualifications, Mr. WEBB moved an amendment providing that a person should not be disqualified from membership of the council of a county or county borough by reason that he or a member of his family had been an inmate of any institution provided under the Lunacy or Mental Deficiency Acts. Mr. Webb said that as the law now stood a man was a pauper if his wife or child had been taken to an asylum even if he had paid the cost of maintenance in that institution when it was charged to him by the guardians. Mr. E. BROWN said that there was some doubt whether relief given for maternity and child welfare in a maternity home constituted relief under the bill. Mr. CHAMBERLAIN said that a maternity home or a similar institution was covered by the words of the clause. So far as the Mental Deficiency Acts were concerned, the point raised by Mr. Webb was quite clear. Under the Mental Deficiency Act of 1913, while the authorities were entitled to recover a sum towards the expenses of the maintenance from the individual they had no power to recover from the guardians. Therefore treatment in a mental deficiency institution was not poor relief. It was true that a pauper lunatic who was confined in an asylum and was chargeable to the guardians was disqualified under certain circumstances but there again one consideration was whether the person was receiving medical or surgical relief. When legislation was introduced to deal with the recommendations of the Royal Commission on the lunacy laws, no doubt the Lunacy Acts would be added to the Acts mentioned in Clause 4 of the Local Government Bill, and there would be a provision under the terms of this bill. Mr. WEBB remarked that it was not fair to disqualify 115,000 people before the passage of lunacy legislation, when the matter could easily be set right now. Mr. CHAMBERLAIN replied that he was not sure that the matter could be easily set right now but he would give it further consideration. The amendment was withdrawn, and Clause 9 was added to the bill.

Clause 10 (repeal of the Unemployed Workman Act 1905) Clause 11 (amendments to certain Acts) and Clause 12 (alteration of the constitution of assessment committees) were then passed under the guillotine, and the debate was adjourned.

In 1926-27 the Poor Law authorities of England and Wales spent according to Sir Kingsley Wood, £10,105,000 on such maintenance and treatment of the sick as will be transferred to the public health authorities under the Local Government Bill.

Proposed Change in Housing Subsidies.

On December 12th, in the House of Commons, Mr. CHAMBERLAIN moved that the draft of the Order proposed to be made by the Minister of Health and the Scottish Board of Health under Section 5 of the Housing Financial Provisions Act be approved. This Order proposes to terminate from next September the grant of subsidies under the 'Chamberlain' Housing Act and to reduce the subsidy payable under the Whitley Act.

Criticizing the proposal, Mr. ARTHUR GREENWOOD quoted from reports by medical officers of health for Birmingham, Stoke-on-Trent and Wandsworth regarding the shortage of houses.

Dr. ELLIOT said the suggested reduction of the subsidy in Scotland was not so great as in England. The housing situation in Scotland was still acute.

Dr. FREMANTLE said the House was considering an expenditure on housing amounting roughly to £10,000,000 a year for from twenty to sixty years apart from any continuance of housing subsidies in the next few years. The medical officers of health asked for grants of £10,000, £20,000 or £50,000 at most to improve the health of the people. If the case for housing was argued from the point of view of improving the health of the people then they would rather spend on other purposes every extra penny proposed to be spent on housing. Every Chancellor had only a limited sum of money to devote to public health services including housing; therefore £100,000 more for housing next year meant £100,000 less for other purposes. Even if this costly way of helping the health of the people were necessary, the House of Commons still had to consider whether it got value for money. The subsidy was an unnatural way of supplying houses and the sooner they got back to normal conditions the better. He hoped that next year it would be possible to deal with the same question as a whole. All housing subsidies should be merged in a block grant to be given to boroughs and housing authorities specifically for their clearances and for the provision of houses for the poorer classes.

Mr. BIRN said that for every boy under 5 years of age who died in a four-roomed house four would die in a single-roomed house. According to the estimates of the Scottish Board of Health there were still 100,000 houses overprovided in Scotland. Other members gave instances of overcrowding and bad housing conditions.

Sir KINGSLEY WOOD in reply said the country was building at the rate of 188,000 houses a year.

A Labour amendment was defeated and the House approved Mr. Chamberlain's resolution.

National Health Insurance

Sir KINGSLEY WOOD, answering Mr. Crooke on December 11th, said that the national health insurance scheme was not financed on the basis of a single fund and the surplus was in the main the aggregation of the surpluses of over 8,000 approved societies and branches. Those surpluses were ascertained by quinquennial valuations the results of which were summarized in the report of the Government actuary. The last of such reports dated November 25th 1926 showed that the total surpluses amounted to £12,413,319 from which amounts totalling £26,619,161 were certified for distribution in additional benefits in the ensuing quinquennium.

Colonel APPLIN asked the Minister of Health whether he was aware of the waste of medicines due to doses being prescribed in drachms and shown on the bottle as tablespoonfuls, and whether seeing that the average tablespoon held 50 per cent more medicine than 4 drachms he would consider a regulation requiring all doses on bottles of medicine supplied under the national health insurance scheme to be shown in drachms and ounces or the issue of a cheap medicine glass. Mr. CHAMBERLAIN said the graduated markings on medicine bottles usually indicated half ounces—that is 4 drachms. His investigation of the prescribing of insurance practitioners did not suggest that medicines were often repeated before the proper time which would be the result of the consumption of over large doses. He did not think the matter one in which he was called upon to interfere.

Relief for Distressed Mining Areas

On December 17th the Prime Minister announced that the Government proposed to ask Parliament for authority to grant to the Lord Mayor's Fund £1 for every £1 received in voluntary subscriptions to the Fund and as an immediate step to grant £150,000 to the Fund as the equivalent of the money already subscribed to it. The Government would also ask Parliament to approve an immediate vote of £100,000 to assist the removal of families from the distressed areas. Opportunity would be given to the House to debate the question before rising for the Christmas recess.

Lord EUSTACE PERCY on December 11th stated that there were twenty-two education authorities in the West Riding. Of these during the week ended December 1st twelve were providing meals for 5,000 children. He had as yet received no official return from the West Riding County Authority, but he understood that they were now feeding about 1,000 children. Of the remaining nine authorities, some were understood to be making preparations for

feeding. Surveys by the authorities' medical officers of the condition of the children were conducted in a number of the areas last summer, and recently in the Barnsley area. The results of the surveys varied considerably in different areas, 8 per cent of the children were found to be malnourished in the districts of the county surveyed and 36 per cent in Barnsley. In Doncaster, Pontefract, Rotherham, and Sheffield the surveys failed to reveal at that time any abnormal conditions. The surveys were concerned primarily with the state of nutrition of the children and he had not the same amount of information in regard to boots and clothing, but they tended to confirm what was generally known as to the unsatisfactory state of the children's boots and clothing in the distressed areas. Thus in the West Riding survey of last summer 21 per cent of the 44,000 children examined were found to have bad boots, in the recent Barnsley survey approximately 6 per cent were returned as badly clothed.

Defence against Poison Gas.—On December 11th Sir I. WORTHINGTON EVANS told Mr. Thurtle that research and experiment relating to defence against gas were directed towards the methods and appliances for individual and collective protection and also towards the treatment of gas casualties. Research and experiments were primarily concerned with defence against gas but it was essential, for the purpose of the protection against gas, to investigate the possibilities of new gases and other forms of chemical warfare which might be illicitly employed against this country. Mr. Thurtle asked whether the secondary reason for these experiments was to discover how gas could be employed offensively. Sir I. WORTHINGTON EVANS said that his answer was a very full one.

Women in Medical Schools.—In an answer to Sir Robert Thomas on December 12th Sir KINGSLEY WOOD said the Minister of Health understood that outside London there was no restriction on the admission of women to medical schools. The position in London already formed the subject of an inquiry initiated by the University of London.

Notes in Brief

Sir J. Gilmour states that the Scottish Board of Health has approved a proposal of the Glasgow and South West of Scotland Joint Committee for the administration of the Blind Persons Act to establish a central clinic for the medical certification of blind persons.

Out of 30 education authorities in Wales, 27 undertake dental service. During 1927 162,605 children were dentally inspected in Wales and 68,345 treated.

Obituary

SIR JOHN PHILLIPS, M.D., F.R.C.P.

Honorary Physician to the Queen, Consulting Obstetric Physician to King's College Hospital.

We had to announce with regret in our last issue the death, on December 8th, of Sir John Phillips, M.D., honorary physician to Queen Mary, consulting obstetric physician to King's College Hospital, and professor emeritus of obstetric medicine at King's College, London.

Born on July 6th, 1855, the eldest son of Zachariah Phillips of Brehmston Manor, Bedford, John Phillips was educated at Bedford Grammar School and at St John's College, Cambridge. In 1877 having graduated B.A., with honours in the Natural Sciences Tripos, he proceeded to his clinical studies at King's College Hospital. In 1879 he obtained the diploma of M.R.C.S. Eng., and took the M.B. degree at Cambridge in 1881. He became M.R.C.P. Lond. in 1885 and proceeded M.A. and M.D. in 1888. Four years later he was elected a Fellow of the Royal College of Physicians of London, and he served on the Council of the College from 1911 to 1915. He was appointed assistant obstetric physician to King's College Hospital in 1889, obstetric physician in 1906, and consulting physician on his retirement from the active staff in 1915. In addition, he had held appointments as consulting physician to the British Lying-in Hospital in Judell Street, and as consulting obstetric physician to the Bromley Cottage Hospital in Kent. Throughout the greater part of his association with King's College Hospital as obstetric physician and gynaecologist he also held the position of professor of obstetric medicine at King's College, being appointed professor emeritus on his retirement. He was elected a Fellow of King's College in 1900. At various periods he served as examiner in midwifery and diseases of women to the Universities of Cambridge, Glasgow, and London, and to the English Conjoint Board. He was knighted at the beginning of 1918, and in March of the same year the Queen appointed him to be her honorary physician.

Sir John Phillips contributed the section on "plastic operations in gynaecology" to Allbutt and Playfair's

System of Gynaecology, and on "vaginal operations" to Cheyne and Buighard's *Operative Surgery*. His book, entitled *Outlines of the Diseases of Women*, reached its fourth edition in 1906. Among his contributions to medical journals may be mentioned papers on the management of the pregnant, parturient, and lying-in woman suffering from cardiac disease, on rupture of the vagina during labour, on hepatic toxæmia complicating pregnancy and labour, and on the therapeutic influence of x-rays on female pelvic disorders. For some years he acted as joint editor of the *King's College Hospital Reports*.

As an obstetrician he was noted for thoroughness and remarkable dexterity, and these qualities, combined with dignity and charm of presence, brought him a large private practice. His method of handling a case from beginning to end was an object lesson to the young accoucheur. In the gynaecological theatre his technique was marked by scrupulous attention to detail and unhurried precision at every stage of the operation.

Sir John Phillips married in 1890, and leaves a son and three daughters, his first wife died in 1917. He married again in 1926. His later years were clouded by progressive failure of sight, leading to almost total blindness.

THE LATE DR MICHAEL DAVITT

We have received from Dr John Mills, honorary secretary of the Connaught Branch, the following appreciation:

The tragically sudden death of Dr Michael Davitt has evoked the widest sympathy of his professional brethren and the general public, not alone in Galway, but throughout Ireland. As a student he had had a career of distinction rarely equalled in the annals of the National University of Ireland, of which he was a graduate, and he achieved a unique place in the affection and regard of his fellow students, being with them in the social and athletic life to the fullest extent. The son of one of the ablest and most disinterested men who has contributed in a very large degree to the making of recent history in Ireland Davitt was very thorough in anything he undertook, and especially made his mark in the devoted work he gave to the organization of the Central Hospital in Galway and its remodelling into a modern hospital from the form of a workhouse, an undertaking begun some few years ago, and entailing a vast amount of thought and care. For the accomplishment of this work Davitt was appointed physician to the Central Hospital, and fulfilled his task so fully and completely that the hospital which now replaces the old Union Hospital is a modern structure which can very favourably challenge comparison with similar ones in much larger towns. He was unremitting in the discharge of his duties, seeking only and always the good of his patients, by whom he was greatly esteemed. His professional colleagues regret a courteous, kindly gentleman, who was always helpful and considerate and who took a real pleasure in assisting a professional colleague. With such a character, alert intellect, and keen interest in the profession he was frequently engaged in consultation.

Universities and Colleges

UNIVERSITY OF OXFORD

At a congregation held on December 17th the following medical degrees were conferred:

D.M.—A. Q. Wills
B.M.—J. C. Neely G. G. Hill Joyce Wright Margaret A. L. Herbertson

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B. B.S.—J. G. W. Ayres * Elizabeth Cooper * H. H. P. Hines worth (University Medal) * C. A. Keesle * H. G. W. Rahn * H. R. Reid S. I. Abraham G. T. Allerton Sophia Antonovitch H.
